LIBRARY ANNEX

All books not in use for instruction or research are limited to all borrowers.

Volumes of periodicals and of pamphlets comprise so many subjects, that they are held in the library as much as possible. For special purposes they are given out for a limited time.

Graduates and seniors are allowed five volumes for two weeks. Other students may have two vols. from the circulating library for two weeks.

Books not needed during recess periods should be returned to the library, or arrangements made for their return during borrower's absence, if wanted.

Books needed by more than one person are held on the reserve list.

Books of special value and gift books, when the giver wishes it, are not allowed to circulate.

Original Lectures.

ON RELAPSING FEVER.

BY A. CLARK, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE I., FEB. 7, 1870.

I PROPOSE to occupy your time to-day in recounting to you the peculiarities of a fever which has appeared among us for the first time. It has been long recognized in England, Scotland, and Ireland, and has prevailed in an epidemic form repeatedly in those countries, and has been carefully studied by their physicians. It has been particularly well investigated by Professor Henderson, in 1843–4, and by Dr. Jenner, in 1847–8. Dr. Jenner proposed for it the name Relapsing Fever. Dr. Henderson, and the physicians who saw the epidemic of which he wrote, called it the "Epidemic Fever." It has been called the Five-day Fever, the Short Fever, the Seven-day Fever, and so by a variety of names. As it is believed to be connected with destitution, it has been sometimes called Famine Fever, though Typhus is more emphatically the Famine Fever. Until now we have seen little of it.

In 1844 a ship reached the port of Philadelphia having on board some sick emigrants. Of the sick passengers fifteen were received into the Philadelphia Hospital, and about the same number into the Pennsylvania Hospital. Those that were received in the Philadelphia Hospital came under the observation of Dr. Clymer, who recognized the disease as the fever that prevailed in 1843–4 in Scotland, and I believe in Ireland —the Relapsing Fever. It appears, however, that the disease was limited on that occasion to the passengers who came in that ship, except that in one instance a passenger had the fever at his own house, and his two sisters afterwards took it and were brought to the Hospital. Beyond this it is not known to have spread. In 1850–51 Dr. Flint, then living in Buffalo, attended quite a large number of emigrants who had typhus fever brought there from abroad, and found in summing up his cases that the results did correspond with the known history of typhus, and with records reported by himself previously. He then reviewed his cases, and threw out fifteen in which there had been relapses, and which he was satisfied were relapsing fever; but not expecting that disease, he had not recognized it at the time of their occurrence. With these two exceptions, it is proper to say, we have not seen the disease here at all. It is true Aitkin refers to Dr. Dubois as having seen cases here, but I do not know to what Dr. Dubois he alludes, and have heard no report of the existence of the disease in this country beyond the two instances I have mentioned.

The fever is so peculiar, so marked in its characteristics, that it can hardly be mistaken. I read at my Hospital clinique the other day the definition given of it by Aitkin. Perhaps I had better read it again:

"A continued fever, having a very abrupt invasion, marked by rigors, chilliness, and severe headache, vomiting, and often jaundice; a white moist tongue, epigastric tenderness, confined bowels, enlarged liver and spleen, high-colored urine, a frequent, full, and often bounding pulse, pains in the back and limbs, restlessness, and occasionally delirium. These symptoms abruptly terminate by an exceedingly copious perspiration, between the fifth and eighth day; and after a complete apyretic interval (during which the patient may be so well as to get up and walk about), an abrupt relapse supervenes on the FOURTEENTH day from the first commencement. The relapse runs a similar course to that of the primary paroxysm, and terminates between the third and eighth day. In some cases a second, third, fourth, or even fifth relapse may occur; death is apt to happen from sudden syncope, especially after the excessive perspiration, or from the suppression of urine, and coma. No constant eruption and no special lesion are associated with this fever."—*Aitkin.*

It is, you observe, a clean-cut description, and you see how much the disease differs from any form of fever we have been accustomed to see here. There are a good many points of difference between it and typhus, and typhoid. These are pointed out by Allison and Henderson. Allison regarded it in 1843 as a variety of typhus. Henderson, witnessing the same disease, attempts to prove, and does prove, that it is a different affection.

Prof. Allison points out the following peculiarities, viz.:—

1. A duration of five to seven days, very rarely extending beyond the ninth, and its termination in a crisis.
2. The absence of the typhus or typhoid eruption.
3. The frequent occurrence of jaundice, with some fulness and tenderness in hepatic region, and vomiting of green or brown matter.
4. The unusual degree of sickness and vomiting.
5. The almost constant occurrence of relapse, which generally took place on the fourteenth day.
6. The termination in the great majority of the cases in profuse critical sweats.
7. Severe muscular pains during and after the sweating, and particularly after the relapse.
8. The mortality, which was very small.
9. In every pregnant woman under his care abortion occurred.

Prof. Henderson, however, says: "It would be highly unphilosophical to refuse to account those, different kinds of fever, and to grant them different appellations, which differ widely, not in degree only, but in the nature of their symptoms, and which cannot be traced to one contagion, but in a very remarkable manner to two." He states that exposure to typhus never produces the "epidemic fever," as the relapsing fever was then called; and that exposure to the "epidemic fever" never produces typhus, but that each produces its like, and nothing else. Prof. Henderson cites cases to show that one of these diseases does not protect the person who has had it against the other. Some were attacked

with typhus soon after they had had the epidemic, and some took the epidemic disease only a few weeks after typhus. He found that when typhus and the epidemic fever were prevailing in the same district of the city, the epidemic fever came to the Infirmary from dwellings where that fever only existed, and never from those infected with typhus, and so contrariwise.

He also contrasts the symptoms of the two diseases, as Dr. Allison did. To him, therefore, is conceded the credit of having first wholly detached relapsing fever from all connection with typhus (which for him at that time included typhoid fever), and giving it the position of a distinct affection.

Prof. Henderson attaches importance to the different rates of the pulse in the two diseases. He found its average frequency in the first five days of typhus was 100 in the minute, while in the first five days of "the epidemic" it was 123. He says that great frequency of pulse in the early stage of typhus is a most alarming symptom, while the same degree of frequency in "the epidemic" is of little prognostic importance, it being often as high as 140 or 145 on the second or third day, without changing the usual favorable course of the disease.

He says that typhus when it reaches its natural limit declines slowly. "Nearly one-third of the whole duration of the febrile state being usually consumed between the period when the fever begins to amend and that of its total cessation." While in the epidemic: "In the ordinary course of things we find the individual who at one visit presented a temperature of 104 or 106, and a pulse of 130 or more, at the next, if the term of his fever had arrived in the interval, with a temperature of 98, and a pulse between 70 and 80."

He holds that a favorable change may coincide with a profuse perspiration in typhus, but never a total cessation of the febrile state, but urges that in the majority of cases such an occurrence "ushers in or accompanies a state of hopeless prostration, stupor, hurried breathing, and increased frequency of pulse." This he contrasts with the copious sweat and the accompanying defervescence of the epidemic fever.

Relapse, using the term to mean "a repetition of the same malady, through which the subject of it has recently passed," Prof. Henderson wholly denies to typhus. In 1,600 or 2,000 cases he had not met with a single instance of it. He had seen febrile attacks during convalescence attending some local inflammatory affection caught in the hospital. He says "it is as absurd to talk of a relapse of typhus fever as it is to talk of a relapse of small-pox or measles." For him, then, the relapse of the epidemic fever was a distinctive. and characteristic fact of relapse.

Now, as regards the possibility of relapse, I take issue with the learned doctor. Having myself been pretty well bathed in the poison of typhus, prescribing at one time for two hundred and fifty hospital patients daily, and that for a score of months, I must have acquired some familiarity with it, and I can tell you there are relapses in typhus fever. I have seen such evidences of it as would convince even Dr. Henderson or Dr. Perry. For example, I remember cases in which there was no local inflammation; in which during convalescence the patients fell sick again with a repetition of the symptoms of the original disease, and in due time there came out the petechial eruption peculiar to that affection.

Then as to a relapse of measles: measles is repeated, and so is scarlet fever sometimes. Dr. Linsly, of this city, will tell you of a family in which a boy had measles contracted at school. It communicated to the other children of the family. After they had all gone through it, the first turn came, and he took it again. This is not properly a relapse, as the word is used in its relation to relapsing fever; still it is a repetition. In that disease relapse is the rule, while in typhus and typhoid fevers it is the exception, and perhaps a rare exception. The New England physicians, who have been long familiar with the typhoid affection of Louis, know that during the convalescence of a patient there frequently occurs a febrile movement which cannot be distinguished from that which the patient has just gone through. It may be gastric fever, or something different from the typhoid in its nature,—for it is not probable that the abdominal lesions are repeated,—still it so resembles the antecedent fever that it would be hard to persuade many of them that it is not a true relapse. However this may be, the distinction that is made by Dr. Henderson is valid, even if there are occasional relapses in the other forms of fever.

The disease has found its victims chiefly among the destitute. It has been called the famine fever. Dr. Bigbie concurs with Dr. Murchison in the opinion that relapsing fever is "the result of destitution, while typhus is produced by destitution and over-crowding combined," and thinks that it "will stand the test of further observation and renewed careful investigation." Dr. Murchison found, on examining the records of the London Fever Hospital, that from 1847 to the time of search, 430, or 97.5 per cent. of all the relapsing fever patients were paupers, whose expenses were paid by parishes. "A large proportion of them, for some time previous to their attack, had been literally starving."

Relapsing fever in Europe is regarded as contagious, or, to respect an old and almost obsolete distinction, infectious. In other words, it is believed that persons in health may, at the bedside of the sick, inhale or otherwise receive into their system poisonous emanations, which will soon produce in them the same relapsing fever. More than this, it is believed by a limited number of physicians that the poison is held and diffused by fomites, and that persons who wash the under garments and bedding of the sick are liable to the disease. Dr. Welsh, of Edinburgh, 1819, quoted by Bigbie, says: "When acting as clerk to Dr. Hamilton in the Royal Infirmary, in the course of four months my three colleagues, two of the young men in the apothecary shop, two house-maids, and thirteen or fourteen nurses, caught the disease, and the matron and one of the dressers died of it. Since I left the Infirmary three more of the gentlemen acting as clerks, one of the young men in the shop, and many more of the nurses, have caught the infection. In this Hospital (Queensbury House) Messrs. Stephenson & Christison, the matron, two apothecaries in succession, the shop-boy, washerwoman, and thirty-eight nurses, have been infected; four of the nurses died. With the exception of two or three nurses, who have been but a short time in the hospital, I am now the only person who has not caught the disease, either here or at the Infirmary, within the last eight or ten months."

Dr. Wardell says of the epidemic of 1843-4: "Most of the medical officers connected with the Edinburgh Royal Infirmary and the additional fever hospitals were seized with it; eight of the resident and clinical clerks in quick succession became affected. . . . . The majority of the nurses and domestics took the disease, and of the former at one time no less than nineteen were laboring under it. Some of the dispensary physicians and other practitioners took the disease, as also several of the clergy and visitors of the sick, whose duties brought them to the bedside."

Dr. Cormack presents a similar picture, and says: "Hardly any of the nurses or laundry women, or

others coming in contact with the patients *or their clothes*, have escaped."

Dr. Bigbie confirms the statements made in these quotations by reference to similar facts in the hospital with which he was connected, and adds: "It appears sufficiently remarkable that, as specially noticed by Dr. Cormack, in 1843–4, laundry women engaged in washing the clothes of the sick, though not brought into direct communication with the patients themselves, suffered frequently from the disease;" or, in other words, he was led to the conclusion that, "*by means of fomites or clothes*, the disease may be readily propagated." Cormack and Bigbie seem thus far to be the only authorities on this question of fomites.

On the authority of Dr. Welsh, it is stated that relapsing fever may be repeated in the same individual. "Being once afflicted with the disease seems to afford little, if any, protection against a second or even a third attack, and that too in the space of a few months. I have seen many instances of a second attack within the last twelve months." This statement should not be admitted without further inquiry; analogy discredits it. Other infectious diseases occur, as a rule, but once. If this affection were an exception to that rule, it is probable that the fact would have been generally noticed and announced. It has occurred to me that Dr. Welsh may have met with some cases of repeated relapse and mistaken them for new attacks; although even second and third relapses do not seem to have been frequently noticed.

Dr. Henderson called attention to the fact that in some of the cases urea is not fully eliminated from the blood. He had a patient who, after the critical sweat, had repeated convulsions, and died. He found urea in the blood and in the serum, which partly filled the lateral ventricles. In another case, confusion of mind, somnolence, and languor followed the sweat; and the blood taken from the arm contained urea in small quantity. In both these there was a moderate diminution in the quantity of urine. The latter case was treated by diuretics and recovered. Mr. Taylor also found urea in the blood of a patient who had cerebral symptoms with diminution of the urinary secretion.

Jaundice, when it occurred in relapsing fever, by some of the British reporters, was regarded as a complication more or less grave; but Prof. Henderson, who participated in this conviction at one time, says: "I am in a condition to assert now that there is no proof that the jaundice is of any consequence—no proof that the jaundice has caused those symptoms of cerebral disorder which have been ascribed to it, or has produced a fatal event in a single instance."

Douglas found this symptom 29 times in 220 cases—equal to about 1 in 8. It occurred in the first attack 19 times, and in the second 10 times. It occurred in none before the fourth day, and in five at the time of the first crisis. Paterson observed it only four times in 141 cases; Jenner in one-fourth of his cases; David Smith in the proportion of 1 to 2.6, nearly. A general average appears to recognize jaundice in one-fourth to one-fifth of all the cases.

The occasional vomiting of black matter Dr. Cormack regarded as a very unfavorable symptom, yet Dr. Anott reports that it was not a very unfrequent occurrence in the Dundee Hospital, where the mortality was only about one per cent., or 7 deaths in 672 cases.

Abortion, Dr. Allison found, took place in every pregnant woman attacked by the fever. Later observers have noticed some exceptions to Allison's rule.

A bronzing, leadening, or purpling of the countenance before and after seizure, referred to by Dr. Cormack, does not seem to have fixed the attention of other observers, and as it is described as a "striking peculiarity noticed by all visitors," it is strange, if it is of any importance, that it should have escaped observation. But Dr. Cormack had the strange conviction that this form of fever was closely allied to the yellow fever of tropical climates. This idea, utterly untenable, may have colored his notion of the importance of this symptom, and also of that of the dark or brown vomiting occasionally met with.

Regarding an eruption, there is some diversity of opinion. Spots on the body, generally differing more or less from those of the typhus and typhoid, have been described as occurring in particular cases. Petechiæ or purpuric spots, ecchymotic, have been occasionally seen by most observers. Sudamina were found in some cases. Douglas found them twelve times in two hundred cases. A large number of cases in the Scotch epidemics, 1843, and in London, 1847, exhibited "an eruption of small spots, round, purple, unaltered by pressure, and extremely like flea-bites;" and the learned, from Allison to Jenner, have been puzzled and confounded in their attempts to determine whether this is the work of the insect or a feature of the disease.

Relapsing fever appears to have been epidemic in Silesia (Prussian and Austrian) in 1847. An eruption of some sort appears to have been frequently seen. One author compares it to flea-bites. Another makes it up of "elevated little round red and yellow spots, which presently became darker colored, became confluent, dark bluish-red, and somewhat ecchymotic, and lasted ten or twelve days unaltered." Again, the flanks, and afterwards the body, presented spots with centres darker than the borders, rosy, or pale-red; disappearing on pressure, of short duration, disappearing after death, or followed by desquamation. Such diversity of eruption cannot be an *essential* feature of one disease. All told, it is well to say with Aitkin, that relapsing fever has "no constant eruption."

The so-called *crisis* does not appear to have been a constant occurrence. In 743 cases treated by Welsh, the improvement was gradual, without any notable discharge, in as many as 95. In 38 of Douglas' 121 cases, the crisis did not occur. Other writers say it almost always occurs. As to the time of its occurrence, it does not appear to have been observed earlier than the fourth day or later than the tenth. Paterson and Jenner place it between the fifth and sixth; Jackson on the eighth. Douglas finds that it falls on the sixth day in females, and on the seventh in males. There is some reason for supposing that it occurs earlier in young persons than in those of mature age.

Relapse, it seems, is not constant. It sounds a little strangely to say that in relapsing fever there is no relapse. But it seems probable that in the European fever a febrile movement was noticed in some, while the epidemic was prevailing, which could not be distinguished from the first paroxysm of relapsing disease, having the same duration, the same symptoms, the same crisis, and thus ended; so that, at the time the relapse was expected, convalescence was not interrupted. David Smith reports that he had 288 such cases in 1,000, while Douglas found only 2 in 220, and he was doubtful even of these two. Almost all the writers say relapse was "almost invariable," substantially admitting that there is a small number of cases in which it does not occur.

The epigastric tenderness was generally present in the European cases, often associated with increased size of the liver, and at the same time of the spleen. There is great uniformity in regard to the latter, all agreeing that the spleen was enlarged in the progress of the disease. It was recognized during the sickness, and demonstrated after death.

The high temperature is a marked feature—not perhaps the absolute temperature, but the rate at which it ascends in the early period of the patient's sickness.

Then the copious perspiration: sometimes the perspiration is not so very profuse, but the concurrence of the defervescence and sweating is the rule at the end of the first paroxysm, and there is a repetition of it at the end of the second, and with it a very rapid subsidence of the symptoms. I shall give you some instances of this concurrence in our own cases directly.

The mortality of "the epidemic fever" was remarkably small. The disease prevailed in 1843–4 in most of the large towns of Scotland. In the Dundee Hospital only one per cent. of those attacked died; in Edinburgh, one in thirty to one in sixty; in Aberdeen, one in thirty-four; in Glasgow, three and a half per cent.; but Dr. David Smith, in the last-named city, treated 1,000 cases, "occurring in the lowest, filthiest, and most densely populated part of the town," with a mortality of 43, which is 4·3 per cent. Dr. Murchison, in his recent book on Fevers, collecting such statistics as were within his reach, reports that in 14,119 cases there were 672 deaths, or 4¾ per cent. As the proportion of deaths has not been the same in different places, so it has varied in different epidemics. It is variously rated at 1 to 8.63 per cent. But the deaths everywhere have been charged more to complications, or concurrent, or pre-existing diseases of other sorts, than to the fever. Still the fever itself causes some deaths. Some die as if by syncope in the period of defervescence; and some die comatose, as if they were poisoned by urea in the blood.

The disease appears to be essentially epidemic, prevailing more or less extensively for a few months to three years, then wholly disappearing for years; yet Murchison believes that between the epidemic of 1843 and that of 1847–8, a few cases of relapsing fever continued to appear both in Ireland and Britain. Its beginnings in each epidemic have not been discovered. It is not certainly known whether it can originate *de novo* in the persons of the destitute, or in the influences that surround them. Typhoid fever, we believe, is produced by a poison from without, as well as a poison from within the body. It may be so with the relapsing fever.

Regarding the *Lesion*—according to Dr. Cormack, the blood drawn during life coagulated imperfectly, forming "a homogeneous spongy mass, in place of a firm fibrinous clot, with supernatant serosity." In twelve cases blood in small quantity for examination was taken from the thumb. Some of the patients were in the pyrexial and some in the apyrexial stage. "In all of them there was an unusual number of pus globules (white corpuscles), and in some, in addition to this, all the globules (blood corpuscles) were found serrated and notched (crenated)."

This observer also found congestions of the mucous membrane of the stomach, and sometimes of the small intestines; he notices also occasional ecchymosis in the stomach.

All the authors found enlargement of the spleen a common occurrence, recognizable during life, as well as after death. Jenner thinks it occurs more frequently than in any other disease. Hypertrophy of the liver is not often mentioned.

The complications that occur in relapsing fever appear to be diarrhœa, dysentery, bronchitis, laryngitis, epistaxis, pneumonia, and pleurisy. Diarrhœa and bronchitis were not uncommon; the rest were rarely met with.

The *sequelæ* seem to be limited to two. The pains resembling those of rheumatism, so common during the disease, are often protracted far into the convalescence; and ophthalmia has in some instances occurred during this stage. This inflammation generally attacks one eye only, and occurs two, three, four weeks or more after the relapse.

This ophthalmia is described by Dr. McKenzie as at first a congestion, "followed by inflammation of the inner parts of the eye, and especially of the retina, producing great imperfection of sight. This is succeeded by evident inflammation of the iris and sclerotica, the disease extends to the capsule of the lens, and sometimes to the lining membrane of the cornea; there can be little doubt that the choroid is also inflamed, while the conjunctiva remains in general but little affected. . . . . The change of color in the iris, the contracted state of the pupil, and the tags of adhesion between the edge of the pupil and the lens, show the part which the iris takes in the disease. The inner membrane of the cornea and the anterior crystalline capsule, especially the latter, are extremely muddy, showing their participation in the inflammation. The whole wall of the aqueous cell seems in some cases as if coated with a thin layer of lymph of yellowish-green color . . . If not promptly combated by appropriate remedies, the cornea and sclerotica become preternaturally flexible under pressure of the finger, showing that the disease has extended to the vitreous body." Dimness of vision occurs early, later when the iris and sclerotica have participated in the inflammation; there are severe pains in and about the eye, particularly at night."

The convalescence, as a rule, is slow, the patient looking pale and feeling feeble for some weeks—I mean convalescence after the fever, not the ophthalmia.

Now, then, having given a sketch of the disease as seen abroad, and referred to the evidences that are cited of its individuality, particularly by Henderson and Jenner, and after them pointed out the difference between this and any other form of fever yet described, we will inquire into facts and cases as they have presented themselves to us, here, in New York. In the first place, I will remark that the earliest case that was recognized was received at Bellevue Hospital on 6th of November last; but it appears that this was not the first case that occurred in the city.

Dr. Harris, the Sanitary Superintendent, is investigating the question whether it originated *de novo* among us, or was imported. He believes he will find the first subject of it in Baxter Street, where certain persons who deal in old clothes reside, when they are here—persons who are continually vibrating between this city and London, carrying on their trade. The disease has been prevalent in London for some months, and it may be, that just as emigrants brought it to Philadelphia, in 1844, where it hardly spread at all, it may have been brought here. However it came, this is the first time the disease has become epidemic in this country. On Thursday evening last we numbered ninety-two cases, and it was then increasing.

Regarding its recent origin and prevalence in London, Dr. Murchison (*Lancet*, Oct. 9, 1869) states, 68 cases were received by the London Fever Hospital from the 1st of May to the 1st of October, inclusive, viz.: 4 in May; 3 in June; 7 in July; 15 in Aug.; 11 in the first half of September, and 30 in the 15 days ending with the 1st day of Oct. Referring to this increase in the daily admissions, he says the disease threatens to become epidemic. He learns that relapsing fever and typhus appeared in East Prussia about the 1st of Jan. 1868; and that relapsing fever prevailed extensively in Berlin during 1868, and the winter of 1868–9. "It is clear," he says, "that relapsing fever was prevailing extensively in Prussia before it appeared in London;"

and although he is not in possession of direct proof that the disease was imported, among other significant facts he says that seven Polish Jews were admitted with relapsing fever into the German Hospital (near London) between Sept. 1, 1868, and February of the present year.

Now let us study our new disease in the light of cases. You will learn its nature by listening with patience and attention to the reading of three or four of them, as they are drawn up by Dr. Sloat, my House Physician. I know cases are always tedious, but facts are the foundation of knowledge. Mark the correspondence between these cases and those that have occurred in Europe:—

CASE I.—Mary Faguin, æt. 30; Ireland; domestic. Admitted to Bellevue Hospital Dec. 27, 1869. Patient is a prisoner from the workhouse, doing service in the hospital. On the morning of Dec. 25th she began to have chilly sensations, headache, and muscular pains in back and lower extremities. A half hour afterwards she became hot, commenced to vomit bilious matters, and the headache became so severe that she had to go to bed. On Dec. 26th was seen by the physician in office. Her pulse was 130; temp. 103; tongue coated, moist; skin moist. She had severe headache, nausea, and vomiting. Was ordered an emetic; afterwards, spts. mindereri.

Dec. 27th. Admitted as a hospital patient. Vomiting has ceased; skin dry. Evening, pulse 126; temp. 103.

Dec. 28th. Vomiting again; skin moist; pulse 120; temp. 103. Complains of headache and muscular pains. Ordered ice, to be swallowed, and a blister to epigastrium. Evening, bowels have moved; pulse and temp. same as morning.

Dec. 29th. Morning, pulse 120; temp. 103. Evening, pulse 130; temp. 103; skin moist; tongue coated and moist; no vomiting.

Dec. 30th. A marked change has occurred; pulse is 80; temp. 97; skin covered with a profuse sweat; face pale; is very weak. Complains of soreness all over the body; bowels open; has some appetite. This is the first remission since fever began.

Dec. 31st. Pulse and temp. normal. Has great pain in back.

Jan. 4th. Up to this morning patient has been very well. Pulse and temp. have been normal, and she has been walking about. Has been taking quinine, 2 grs. three times a day, since 31st ult. To-day she began to have some chilly sensations again, and a return of the feeling of soreness. Evening; pulse 136; temp. 103½; tongue dry and brown.

Jan. 5th. Pulse 130; temp. 103; skin is moist. Complains of severe headache. Evening, no change.

Jan. 6th. Is slightly jaundiced; face decidedly yellow; pulse 130, and temp. 103 again.

Jan. 7th. Pulse 125; temp. 102½ at 10 A.M. 7 P.M. Free from fever; skin covered with profuse perspiration; tongue is coated; is much prostrated; skin and conjunctiva still keep their yellow hue.

Jan. 13th. Since 7th she has been entirely free from fever. Appetite is much better, but she is still very weak. Rheumatic pains did not leave her till yesterday. Skin has cleared up; bowels are regular.

You will notice that on the evening of the fifth day the fever existed in full force—the pulse and temperature at their maximum, 130 and 103°. On the morning of the sixth day the pulse had fallen to 80, and the temperature to 97°, and there was a profuse perspiration. Then again, 11½ days from the commencement of the first attack (not fourteen, though I shall cite cases in which the period from attack to relapse was just fourteen days), we find the pulse 136, and the temperature at 103½°. For three full days the fever rages, then ceases almost suddenly with perspiration, not to recur again. This is relapsing fever, though the recurrence was of shorter duration than in any of the other sixteen cases of which I intend to give you a sketch.

A CLINICAL LECTURE ON RELAPSING FEVER.

DELIVERED IN BELLEVUE HOSPITAL JAN. 11, 1870,

BY ALFRED L. LOOMIS, M.D.,

PROF. OF INSTITUTES AND PRACTICE OF MEDICINE IN THE MEDICAL DEPARTMENT OF THE NEW YORK UNIVERSITY.

GENTLEMEN—To-day I will call your attention to a form of fever which probably has never before occurred in this hospital, and which made its appearance nearly two months ago; at least I find no cases recorded in the hospital books, and I have never before met with it. In every respect it answers to the description of Relapsing Fever given by English writers.

Before showing you a patient suffering from this disease, or giving you the histories of those who have been ill with it, I will give a brief synopsis of its written history. So far as personal observation is concerned, to me it is a new disease, and its true nature was not recognized until a number of cases had occurred.

More than a century ago in Dublin, Relapsing Fever was recognized and described by Dr. Rutty, since which time it has prevailed as an epidemic in all the northern countries of Europe, and in this country a few cases have been recorded.

Etiology.—As regards its etiology. Among observers there has been great diversity of opinion; but, with the accumulated evidence of the present day, its contagious nature scarcely admits of doubt. Dr. Murchison is of the opinion that relapsing fever is the result of destitution; while typhus fever is produced by overcrowding and destitution combined. There can be little doubt but that it is a distinct type of fever; and although in some of its phenomena it resembles typhus, and in others malarial fever, yet it is neither typhus nor malarial fever.

Symptoms.—Its invasion is almost always sudden, and is marked by chills or rigors, frontal headache, pain in back and limbs, lassitude, and a giddiness which compels the patient to take his bed. The chill lasts from one-fourth of an hour to several hours, and is followed by a hot skin, increased headache, and severe arthritic pains; thirst intense; tongue white; appetite lost, nausea and vomiting frequent, accompanied by pain in epigastrium; the matter vomited consists of ingesta, frequently tinged with bile; sometimes it resembles black vomit. The mind is usually clear; in some instances there is violent delirium. The temperature rises to 104° or 108°; the pulse early runs over 100 to 120, 140, 160, not usually higher on the second than on the first day. The symptoms at night are aggravated. Occasionally the heat of skin is relieved by irregular sweatings, but the other symptoms suffer no abatement. As the disease progresses the patient becomes more prostrate; pulse more rapid and tense; tongue more thickly coated, and sometimes brown and dry. Temperature may rise to 109°. There is no characteristic eruption, although a rose rash is often present for a few hours, or a day or two. The skin is frequently jaundiced from slight to deep yellow; the liver sometimes, the spleen more frequently is enlarged.

At the end of a week, sometimes as early as the third or fifth day, a marked remission of symptoms occurs; a

copious sweat breaks out, and almost immediately afterwards the whole phenomena of fever suddenly vanish, leaving the patient unexpectedly free from the painful symptoms with which a few hours before he had been harassed. The pulse comes down in a few hours from 140 to 70 or less; the temperature from 107° to 98°. Sometimes, instead of a profuse sweat marking the remission, there is an alarming epistaxis—diarrhœa, menorrhagia, or hemorrhage from the bowels.

The patient now feels perfectly well except that he is weak; his appetite returns, his pulse ranges from 50 to 70 per minute, and he gradually gains strength. This apparent convalescence is, however, of not long duration; for after a week, generally on the twelfth or twentieth day of the disease, without warning, a sudden relapse occurs, accompanied by the same phenomena as attended the primary fever; the pulse may rise in a few hours from 70 to 120—140. The symptoms of this stage of the disease are sometimes milder, sometimes more severe than at first. The *relapse* usually lasts three days, may last from one to five. In some instances there is no relapse, or merely one of a few hours' duration. Occasionally a second, sometimes a third or fourth occurs.

Prognosis.—One in twenty-five or fifty die. Death may occur from sudden syncope; from suppression of urine, convulsions and coma, and from complications. Pregnant women invariably abort; abortion sometimes, not always, cause of death; child always still-born (according to Murchison).

Diagnosis.—It differs from other forms of fever: first, in its sudden invasion, and in the sudden rise in pulse and temperature on the first day; second, by the short duration of the primary fever, and its termination by an evident crisis; third, by the almost uniform occurrence of a relapse—occasionally a second and third; fourth, by the frequent occurrence of jaundice; fifth, by the absence of any characteristic eruptions.

Complications.—Sudden syncope may occur during the paroxysms, in the intermission, or in the relapse; not unfrequently it is the result of hemorrhage, and sometimes proves fatal. The most frequent form of hemorrhage is epistaxis; it may, however, take place from the womb, the stomach, the intestines, ears, &c. Laryngitis, bronchitis, pneumonia, and pleurisy occasionally occur as complications. Diarrhœa and dysentery are common, and not an unfrequent cause of death. Muscular and arthritic pains are often more severe during convalescence than during paroxysm. Œdema of lower extremities and glandular swellings are of frequent occurrence. Post-febrile ophthalmia frequently comes on from three weeks to three months after convalescence; at first attended by amaurotic symptoms, afterward by inflammatory. Inflammation apparently commences in retina, then spreads to iris, sclerotic, capsule of lens, choroid, and lining membrane of cornea; conjunctiva usually little affected; recovery slow; sight sometimes lost.

Pathology.—No special anatomical lesion has been found so invariably present as to indicate the anatomical character of the disease.

Treatment.—Dr. Rutty, in the first description of this disease, stated that all who were abandoned to God's good providence and the use of whey, recovered. Although nearly a century has elapsed since this statement was made, no settled plan of treatment has been adopted by the profession. Certain am I that the cases that have come under my observation have apparently been in no way affected by the different remedial agents employed.

I will now present to you the lad J. Cavanaugh, who two days ago passed his second crisis. As you notice, he presents an extremely anæmic appearance, and complains of excessive weakness. His pulse to-day is 60 per minute, and his temperature 98°. His tongue is clean and his appetite good. Two days ago his pulse was 140 and his temperature 105°, his tongue coated, and his appetite lost.

Dr. Stephen Pierson, my House Physician, will now read his history in connection with the histories of other cases that have occurred during my service.*

Case I.—M. R——, æt. 18; single; Irish domestic. Admitted Nov. 15th, 1869, to Ward 21. Been living under very bad hygienic influences.

Nov. 10th. Pains all over body; intense headache; chilliness, lasting five or six hours; sharp febrile action succeeding.

Nov. 11th. Pains and fever continue.

Nov. 12th. Diarrhœa added.

Nov. 15th. On admission, face flushed, tongue coated, diarrhœa; no physical signs of disease in any viscus. Temperature not recorded.

Nov. 16th. Eyes suffused; epistaxis; diarrhœa; tenderness in right iliac fossa; no eruption; subsultus tendinum; pulse 128; temp. 105°; urine normal.

Nov. 17th. Two large watery stools; delirious; pulse 104, temp. 103°.

Nov. 18th. Epistaxis in the morning; in the evening sweating profusely; pulse 76; skin cool; "feels well."

Nov. 24th. Since last note, appetite excellent; pulse 68—88; temp. once in the evening 102°; usually 98°.

Nov. 25th. Pulse 132; temp. 107°; bowels open.

Nov. 26th. Symptoms same.

Nov. 27th. Epistaxis; menses unusually abundant; pulse 128; temp. 107°; severe pain in back, legs, and arms.

Nov. 29th. Sweated profusely and fever subsided; complains of pains and great prostration.

Dec. 8th. Convalescence has advanced rapidly, and patient asks for her discharge.

Treatment during first attack, acid carbolic cryst. gr. ¾ every 4 hours; during relapse, quin. sulph. grs. vi. daily.

This patient, her brother, and her mother were admitted upon the same day; the mother suffering from erysipelas of the leg. The brother had been ill for two or three weeks with a fever, and upon admission was exceedingly weak. He was not asked if there had been a complete intermission, followed by a relapse, in his own case. During his stay in the hospital, Frank C——, also a patient, was much about his bed. On Nov. 27th Frank was seized with chills, quickly followed by a sharp fever lasting four days; was delirious. On the morning of the fifth day he began to sweat profusely; his pulse dropped suddenly to 68, temperature to 94°. He convalesced slowly; complained of rheumatic pains; he is still in the ward, but has had no relapse. Treatment, mineral acids; no quinine.

John A——, a patient in the same ward, already under the influence of quinine for a non-febrile disorder, was on Nov. 23d seized with a chill, intense headache, and sharp fever; this continued four days, and subsided after a profuse sweat.

Dec. 10th. Return of same symptoms, lasting three days; disappearing in the same way, and followed by slow convalescence and pains in limbs. Treatment, mineral acids, and no quinine. Each of the patients last named had been in the wards three weeks before the admission of the Rogers family.

Case II.—Kate ——, night-nurse in Bellevue Hospital, and doing duty in the ward where Case I. lay.

* These histories were furnished me by Dr. Pierson about one week after the delivery of this lecture.

Nov. 22*d.* Sharp chill, succeeded by slight fever; chilliness for twenty-four hours; pains and aches; severe headache.

Nov. 24*th.* Nausea, vomiting, high fever, mild sweats; irregular.

Nov. 25*th.* Fever continues; hemorrhage from vulva; not the time for the menstrual flow.

Nov. 26*th.* Profuse perspiration; chilliness and fever alternate; a little delirious.

Nov. 29*th.* Fever suddenly subsided, leaving patient very weak; hemorrhage from vulva ceased to-day; very weak.

Dec. 6*th.* Had returned to duty. To-day chills and all the former symptoms, including flow of blood, reappeared.

Dec. 10*th.* Fever again suddenly disappeared; profuse perspiration. Treatment during first attack, large doses of quinine; during relapse, hydrochloric acid and small doses of quinine, vi. grs. daily.

CASE III.—Jas. C——, æt. 15; single; New York. No occupation; admitted Dec. 26, 1869, to Ward 14. He has been insufficiently nourished for past four or five months. No home; sleeping in alley-ways and cellars.

Dec. 23*d.* Chilliness; fever pains; constipation.

Dec. 26*th.* On admission, temp. 105°, pulse 132; evening temp. 105°, pulse 132.

Dec. 27*th.* Morning and evening temp. 104°, pulse 132.

Dec. 28*th.* Morning and evening temp. 96°; is not sweating; severe pain in legs; very weak.

Jan. 4*th.* Until to-day convalescence seemed well established. To-day chilliness, fever, little sweats, and then a high persistent fever; temp. 108⅕°, pulse 136.

Jan. 7*th.* Symptoms continue; temp. 107°; pulse from 130—150.

Jan. 8*th.* Been sweating profusely; temp. 98°.

Jan. 9*th.* Very weak; pains all over, and stiffness of joints. No eruption on abdomen at any time. Treatment, first attack, tr. aconit. rad. Treatment second attack, a placebo.

Jan. 24*th.* Discharged well.

CASE IV.—Rosanna P——, æt. 35; married; Ireland. Admitted to Ward 20, Dec. 31st.

Dec. 28*th.* Chills, fever, abdominal tenderness, diarrhœa, intense headache; no epistaxis.

Jan. 2*d.* Fever continued until to-day; no eruption last night; watery passages from bowels, very frequent and large; temp. 97°, pulse 76.

Jan. 12*th.* Return of chills, aches and pains, with fever.

Jan. 13*th.* Headache intense; nausea, vomiting; temp. 104⅕°, pulse 124.

Jan. 14*th.* Temp. 104°, pulse 120.

Jan. 15*th.* Temp. 105°; pulse 150, weak and fluttering; ordered stimulants *pro re nata;* 10 P.M., sweating.

Jan. 16*th.* Sweated profusely; temp. 96°, pulse 64; is very much prostrated; pains in joints very annoying.

Jan. 24*th.* No return of fever. Treatment, mineral acids, quinine grs. iv. three times daily, continued faithfully during the whole apyrexial period.

This patient was a hard character, and was an inmate of the workhouse when admitted to the ward.

CASE V.—Rose M——, æt. 35; married; Ireland; domestic. Admitted to Ward 21, Dec. 23d, four days ago; chills, fever, headache, &c. Attack was subsiding when she entered the hospital.

Jan. 1*st.* Relapse began; fever continued unabated; temp. ranging from 104° to 106° until Jan. 6th, when, after a profuse perspiration, temp. was 97°; pulse 72; did not complain of articular symptoms. Treatment, hydrochloric acid and quinine in small doses from the date of admission.

Jan. 18*th.* Discharged.

CASE VI.—Mary W——, æt. 35; England; widow; domestic. Admitted Nov. 20th to Ward 20. Fever, headache, pains, and constipation; had lasted five days before admission.

Nov. 22*d.* Temp., which has been steadily at 104⅕° or 105⅕°, is falling gradually; abdominal tenderness.

Nov. 23*d.* Perspiring freely; acid odor; pulse 72, small; temp. not taken. Menses for the first time in six months.

Nov. 30*th.* No return of fever, though temp. has been up to 100° and 101° in the evening.

Nov. 31*st.* Relapse beginning; chilly; pulse 100, temp. 104⅕°.

Dec. 2*d.* Temp. has been from 104° to 105°.

Dec. 3*d.* Temp. 97⅕°, pulse 72; perspiring freely. Treatment, acid carbolic cryst. grs. ½ every four hours. Had no return of fever.

CASE VII.—Mary S——, æt. 32; single; Germany; domestic; admitted to Ward 21, Dec. 1st. Seven days ago malaise chills, fever; fever continuing until admission when temp. was 104°, pulse 108.

Dec. 2*d.* Temp. 105⅕. Quin. grs. iv. three times daily.

Dec. 3*d.* Temp. 102⅕°. Tepid sponging; is menstruating.

Dec. 4*th.* Temp. 98°. Sweating freely.

Dec. 12*th.* Chilly; skin hot.

Dec. 16*th.* Temp. 104°; since the 12th it has remained between 103⅕° and 104⅕°.

Dec. 17*th.* Sweats freely; is again losing blood from the vulva. Temp. 97°.

Convalesced steadily, but slowly; no mention of pains. Treatment during the relapse, mineral acids and no quinine.

CASE VIII. Mary W——, æt. 35, single, Ireland, domestic. Admitted Dec. 20th.

Dec. 13*th.* Attack began.

Dec. 21*st.* Sweating profusely; sudamina; temp. 97°.

Dec. 29*th.* Relapse began. Temp. 106°.

Jan. 5*th.* Temp. 99°, pulse 78; she is very weak. Convalesced steadily. Treatment, placebo.

These cases all occurred upon the 1st Medical Division. In every case the patient was fed liberally upon milk and beef-tea. In one or two cases stimulants were resorted to. From questions addressed to the patients themselves the existence of similar fevers in the neighborhood from which they came could not be ascertained with any degree of certainty.

Dr. Moore, House Physician, 3d Medical Division, reports twelve cases in his wards since November 1st. Two of the twelve occurred in patients and employées already in the hospital.

Dr. Sproat, House Physician, 2d Medical Division, reports ten cases, one of which arose in the hospital.

Dr. R——, one of the resident staff, and serving upon the 2d Medical Division, passed through a well-marked course of the same fever. First attack, Dec. 23d, lasting six days. Relapse on the 14th day, lasting three days.

Dr. Graham, House Physician of the Lying-in Division, reports one case in his service, which arose in the hospital, and during which the patient miscarried at the seventh month. The child lived several hours after birth.

Dr. P——, a member of the House Staff, under whose charge was the last-mentioned patient, on January 3d

was seized with chills, followed by a high continued fever. He left the hospital for his home in the country. The fever continued five days, and left him very weak, and annoyed by persistent and severe pains in the joints and muscles. He had no relapse.

In all, thirty-five or thirty-six cases of this peculiar fever have been treated in this hospital since November 1st. One death has occurred. The only marked lesions found at the post-mortem examination was an enlargement of the spleen, which contained several hemorrhagic infarctions of small size.

In all these cases the initial symptom was a chill, followed by the usual phenomena of the disease.

In one case, during a relapse, the pulse is noted as having reached 150 beats; but in the greater number of cases to have varied between 120 and 130.

The temperature in these cases ranged from 102½° to 108½°, but in the majority it only reached 105° during the course of the disease. It seems to have fallen somewhat gradually in only one of the cases where the temperature is noted (Case VII.). Of the ten cases whose histories are particularly recorded, in eight the cessation of the fever was preceded by profuse sweating; in one no sweating occurred; and in the other, large watery passages from the bowels were the critical phenomena. The duration of the primary fever has a margin in the twelve cases of 4 to 10 days; that of the interval, of 7 to 14 days; that of the relapse, of 2 to 7 days.

In only two out of twelve cases was convalescence interrupted by a relapse. Epistaxis, diarrhœa, menorrhagia or severe muscular and arthritic pains, sudamina (in one case), and premature labor, are noted as complications.

The child born at seven months is stated to have lived several hours, a fact which contradicts a statement made by Dr. Murchison that it is invariably still-born.

The epistaxis and hemorrhage from the womb do not seem to have been markedly critical.

An interesting feature in the history of these cases is the duration of the interval between the arrival of the Rogers family and the occurrence of the disease in the two boys and the night-nurse. This interval in the latter case was seven days, in the former cases eight and twelve days. Supposing that they contracted the disease from these people, and on their arrival at the hospital, then the incubative period of the disease varied from seven to twelve days. While tolerably sure of the former fact, we are not so certain of the latter.

On investigating the history of the Rogers family, it was found that, previous to his illness, the boy had been living at No. 90 Madison street. The house was a three-story brick building, in bad repair. The boy lived on the third floor, in a small, not over-clean room. It seems that a woman named Ellen Armstrong or Gibbon (at present residing at No. 71 Cherry street) was sick at this house for some two weeks previous to the boy's illness; that, one Sunday afternoon, for some cause, he went to Bellevue Hospital; on coming home he lay on the bed with this woman; that, one week afterward, he was taken sick with the initial symptoms of the disease. Very soon after this the sister, who had been living as servant in Catherine street, in a clean though small house, and one at which they had and have had no sickness, came home to nurse her brother. Just one week later she was also seized with the disease. About this time the woman Ellen Armstrong, according to the account of the people, was sent to Charity Hospital, but really to the workhouse, from which place she was transferred to Charity Hospital for mucous patches, but no mention is made of fever. This woman's child was sent to 71 Cherry street, to the top floor of a small, dirty two-story and attic building. The inmates of the room to which the child went were a man, his wife and daughter. The child (as I recall the conversation) about one week after its arrival was taken sick with a fever, which lasted two weeks. One week later the man and his wife, and two weeks later the daughter, contracted a fever which, according to their story, was intermittent, but one which confined them to bed from two to three weeks.

They state that at present, at 69 Cherry street, in the house adjoining theirs, separated by a thin partition wall, there is a case of fever.

It will be noticed, that if the boy either took the disease from Ellen Armstrong, or contracted it at Bellevue Hospital on his visit there, the incubation was 7 days. The same holds true of the Rogers girl. But the baby of this woman Ellen Armstrong, if it had this fever, either did not take it upon first exposure, or else it had a longer incubative stage. Again, if the people in the room to which this child was sent had this form of fever, which seems probable, then the incubative period would in two cases be 7 days, and in one case 14 days, with the proviso mentioned.

In the January number of the London *Lancet*, I notice a communication from Dr. Murchison, calling the attention of the profession to the fact that relapsing fever had reappeared in England after an absence of fourteen years, and that there was reason to fear they were on the eve of another epidemic. Although as yet we have been unable to trace the disease to importation, yet, from the locality in which thus far the cases have originated, there is strong presumptive evidence that such is the case.

I am informed by Dr. E. Janeway, one of the Visiting Physicians of Charity Hospital, that since the 15th of January, 35 cases of relapsing fever have occurred in that institution. Of this number three have died. In one were found the following lesions: serous effusion in the ventricles of the brain, thickening of the ependyma, loss of the gray matter on the surface of one corpus striatum at its outer part, and a cyst in its interior; pneumonia involving both lungs, but to a moderate extent; spleen slightly enlarged and softened. The other organs presented nothing special. In the second case was found fibrous induration at the apices of both lungs; recent fibrinous exudation on the right pleura. The right lung was much congested at its base, and the left lung was œdematous at its lower part. The liver weighed 5 lbs. 3 oz., and was soft. The spleen weighed 1 lb. 13 oz., and was soft. The kidneys are stated to have been somewhat granular.

Both of these cases died during the relapse. No satisfactory history could be obtained from the first, as he appeared to be idiotic, and the lesions found in the brain evidently were of old date. In the third case, the liver and spleen were enlarged, and the epithelium of the kidneys was in a state of granular degeneration.

MANAGEMENT OF PLACENTA PRÆVIA.—Dr. H. L. W. Burritt, Bridgeport, Ct. (*Med. and Surg. Reporter*), publishes five cases of placenta prævia, and from his experience he is led to prefer immediate, forcible dilatation of the os and turning, to bring the fœtus by the feet as soon as possible, thinking even greater force safer than delay in a large proportion of these cases. As adjuvants in all cases of uterine hemorrhage, he prefers the acetate of lead and morphia in large doses—or, in relaxed cases, ergot—as an alternative.

Original Communications.

THE AVAILABILITY OF THE SPHYGMOGRAPH,

WITH DESCRIPTION OF A NEW INSTRUMENT.

By E. HOLDEN, M.D.,

NEWARK, N. J.

[Referred for publication by Essex County Medical Society.]

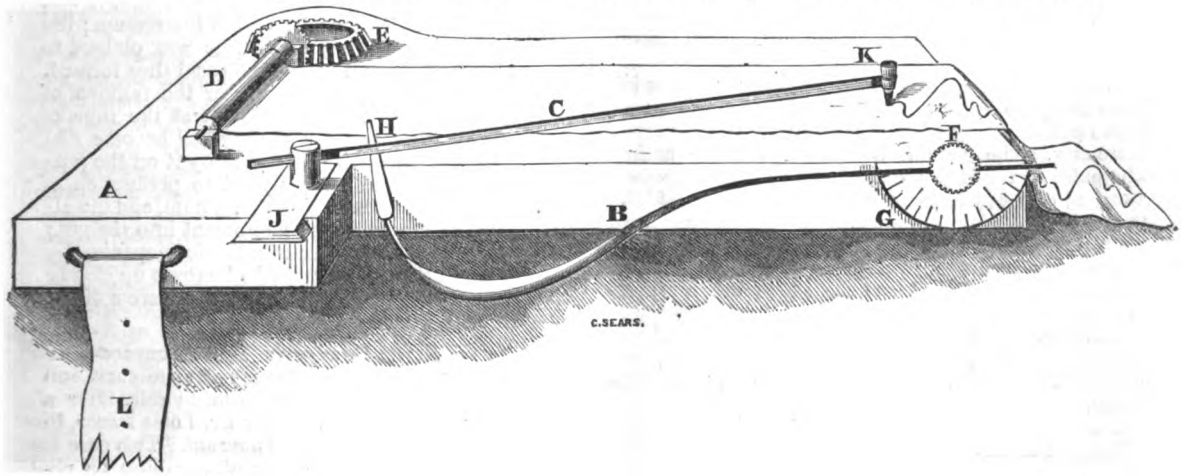
There can be no doubt that a certain indescribable sensation conveyed by the touch of a patient's pulse may give to one physician a skill of diagnosis that another could never acquire; and whoever can place this sensation, or its equivalent, adjuvant as it is of skill, within the reach of all, and can thus supply the tactus eruditus to the junior physician just entering on his journey of painful experiences, as well as to the less acute among the seniors of the medical fraternity, must confer a blessing. That a sphygmograph may be made to accomplish this, will, I believe, be yet demonstrated, and the sanguine hopes of Marey, its originator, more than realized.

Simplicity, with delicacy of sensibility and accurate record, are the great desiderata, and improvement in these will add to the prospect of usefulness of the instrument. The contributions of B. W. Foster, J. B. Sanderson, F. E. Anstie, and F. W. Grimshaw (and perhaps of others also), have done much to give rank to observations conducted by its aid as a branch of science; but the good that may accrue will be small indeed so long as medical men at large are debarred from its use by the two obstacles that now exist, viz.: the great expense of the instrument and its possible inaccuracy.

Reasonably it was hoped that in this automatic recorder we should have a certain means of distinguishing between perplexing symptoms in many cases, and especially in relation to the heart's action, that have not infrequently led to diverse opinions among eminent authorities, leaving the patient alternating between the hope inspired by the one who pronounces his disease functional and the other who says "organic."

Now, while the best of instruments has thus far failed to afford a certain means of diagnosis, there is yet the possibility, either by the multitude of observations and the multiplication of observers, or by increasing the accuracy and delicacy of the instrument, to attain the end, and not only aid in diagnosis, but furnish a means of prognosis most satisfactory and real.

As a contribution to the cause, I desire to present a new form of sphygmograph that differs from the one considered as the standard in its main features, viz.: its pulse spring, measurer of pressure, and tracer.



A. Body of the instrument.
B. Pulse spring.
C. Tracer.
D. Roller for paper.
E. Cog-wheel moved by internal watch-work.
F. Milled screw for regulating pressure.
G. Dial.
H. Impinging cone.
J. Sliding attachment of tracer.
K. Pen.
L. Strap for binding to the wrist or leg.

The first idea, however, that would, I think, present itself to any one, as it did to me, desirous of making an instrument to combine cheapness and accuracy, is that in electricity and the sensitive galvanometer lie the elements, and that adaptation is easy.

It is in fact hard to divest one's self of the belief that an instrument could be thus made, sensitive beyond expression, and perfectly accurate. The galvanometer moves to an electric current inconceivably minute—the contact of two metals, the daily variations of temperature, even the actinic rays of the fixed stars, may be made to record themselves before the observer. A compass with its needle plainly visible, a slip of copper that will rise and fall under the beatings of the pulse and impinge upon a minute bar of silver, and a conducting wire, are all that are essential; compactness is easy, and at once we have an instrument sensitive to a fault.

Multiplication of the coils about the needle, in accordance with a well-known philosophical principle, magnifies its power, and the needle can carry a tracer; and a simple weight or watch-work, the paper to receive the writing.

Unfortunately, however, the delicacy lies entirely in the instrument, and not in its power to record the fine variations in the pulse wave. No modification has seemed in my hands to obviate the one great difficulty—that the instant of generation of the current commences a tracing which is incapable of noting the fine shades of the cardiac and arterial impulse. Changes of temperature, the prevalence of electrical storms, and the many other disturbers of electrical currents, render inaccuracy liable, and an attempt to graduate the current induced by making one of the poles of several metals differing in galvanic power involved a necessary limit to the power of recording infinitesimal changes. The

agent seems, therefore, not after all the one to supplant the admirable recorder of Marey and his imitators.

To render intelligible the object of departure from or modifications of the standard and perhaps familiar instrument, it is necessary to refer to its mechanism and defects. It may be simply described as having first a slip of paper moved by watch-work in a vertical position, like a miniature panorama. Against this, like the stick of the exhibitor, moves the tracing pen, a slender rod of steel, pivoted at its extremity, and touching close to this pivot the distal end of the pulse spring.

The pressure, necessarily variable in different persons, is regulated by a vertical screw which was originally without index. As the pressure, however, was found to make an important difference in the tracing, an index was added by B. W. Foster, of London, and another proposed by Dr. Sanderson.

In this feature of the instrument lies its defect. As the pressure is increased, accuracy is diminished. In the improvement of Dr. Foster, the increase of pressure interferes mechanically with the free action of the pulse spring; in that of Dr. Sanderson (which simply proposes making the pressure screw a fixture and lifting the end of the instrument by inserting slips of brass) the objection lies in the fact of uncertainty when employed by different observers.

The defect is a vital one, since in the niceties of the tracings lies the value of the record.

In the instrument now presented, the paper to receive the tracing moves horizontally by weight or watch-work, the works of an ordinary watch being easily adapted.

The tracer moves like an ordinary pen, and the ink flows freely by its own gravity. This tracer is moved from right to left by a cone impinging near its attached extremity. The cone is a part of the pulse spring. The pulse spring is free, except at its distal end, where attached to the instrument by a milled screw head, by turning which the pressure is regulated and recorded upon a dial.

The body of the instrument is of wood, the tracer and pulse spring of steel, and the whole not expensive to manufacture.

The possible variation lies in the width only of the tracing—an amplification not objectionable, and controlled by the sliding attachment of the flexible tracer.

The drawing will explain itself with this description. The instrument is being made by Tiemann.

Progress of Medical Science.

Dr. Barnes on Uterine Hemorrhage.—When compression, cold, and ergot of rye fail to produce stoppage of post-partum uterine hemorrhage, owing to loss of nerve power, Dr. Barnes recommends the injection of the perchloride of iron before collapse sets in. Dr. Tyler Smith recommends a full dose of ergot of rye, immediately after the birth of the child, to prevent hemorrhage.

Useful Effects of Ipecacuanha in Hæmoptysis.—During the month of October cases of phthisis were, as usual, extremely prevalent in the Paris hospitals. In several cases a remarkable liability to hæmoptysis was observed under the influence of the then reigning "medical constitution." In a great many instances this symptom was most happily amended by the employment of strong doses of ipecacuanha—as much as four grammes, in a gum julep, given in two tablespoonfuls every hour.

Diphtheria and Statistics of Tracheotomy.—Twelve deaths out of twenty-nine cases of diphtheria are inscribed on the register of the Paris hospitals for the month of October—a proportion exceeding that of the former month.

Tracheotomy was performed in seventeen cases, and was successful in five only. Besides, it must be added, that even in these cases the success could not be surely stated, as the parents sometimes remove their children from the hospital before a cure has definitely taken place. In the unsuccessful cases of tracheotomy death occurred immediately after the operation, or it was brought on by broncho-pneumonia.

Pessary Removed from the Rectum.—Dr. Geo. C. Harlan, of Philadelphia (*Am. Jour. of Obstetrics*), presented to the Philadelphia Obstetrical Society a much eroded and bent ring pessary, which he had removed from the rectum of a patient, and gave the subjoined history of the case:—

The woman had had the instrument introduced into the vagina five years ago, for the relief of procidentia uteri, and had worn it with great comfort for two years, when she had a severe fall, since which time she has had considerable pelvic pain, accompanied by a bearing-down sensation. Latterly the pains had increased in severity, and had become complicated by difficulty and distress in defecation. When Dr. H. was called to her he found a portion of the instrument protruding from the anus, and on examination found that it was firmly embedded in the anterior wall of the rectum; the tissue having united firmly over it, he was obliged to cut the ring and draw it out of the canal thus formed. No recto-vaginal fistula was left after the removal of the instrument. Dr. H. believed that at the time of her fall, three years ago, the pessary had become displaced, and that the pressure exerted by it on the posterior vaginal wall had gradually led to perforation of the septum between the vagina and rectum, and the almost complete escape of the instrument into the gut; and he explained the absence of a fistulous opening by the supposition that the tissues had grown up closely around the ring, so that at no time was there a direct communication between the two passages.

A Case of Retro-Curvation and Anchylosis of Knee.—An interesting and rare case of retro-curvation pertaining to the knee-joint, with anchylosis, after a penetrating wound, is published by Dr. Louis Bauer, in the *St. Louis Med. and Surgical Journal*. This case is the first he has personally observed, nor does he remember that there are more than two cases of this nature on record, one by Wm. Adams, of London, the other by Dr. T. E. Grant, of Ottawa, Canada.

Treatment of Rickets.—Dr. Holmes Coote, of St. Bartholomew's Hospital, arranges the treatment of rickets under three heads—hygienic, therapeutic, and mechanical. For the first he advises pure country air, light out-door exercise, and light nutritious diet, with but a small proportion of meat. The second indication is fulfilled by small doses of antimony to recover febrile symptoms, and afterwards a cautious use of tonics. The mechanical treatment includes movable couches on which the patient can be wheeled pleasantly from place to place. Where there is great curvature of the long bones, Mr. Coote sometimes removes a wedge of bone by a subperiosteal operation.

Bromide of Potassium in Epilepsy.—Dr. McGregor, of Edinburgh, reports that out of one hundred and fifty cases of epilepsy he has not been able to cure one by bromide of potassium, though he has found it a very valuable agent in the mitigation of the disease.

DRUGS IN ORGANIC GROWTHS.—Dr. Alfred Meadows contributes a paper to the *Practitioner* on the uselessness of drugs in the treatment of organic growths. He believes that little good and much harm results from their administration in these affections. He supports his opinion by able argument and large experience.

A NEW REMEDY FOR ITCH.—Dr. Spencer, of Oxford, states that he has succeeded in curing itch as speedily and as certainly by iodide of potassium ointment as by sulphur. The ointment is well rubbed in night and morning, for a few days.

COPPER *versus* CHOLERA.—At a recent meeting of the London Clinical Society, it was stated by Dr. Clapton that his investigations on the effects of copper upon the system had elicited the remarkable fact that men engaged at the various copper-works in London always escaped cholera and choleraic diarrhœa during great epidemics. That such an immunity is really afforded by the action of this metal seems now to be a well-attested fact, since Dr. Clapton's statements have lately been confirmed by some statistics communicated by M. Burq to the French Academy of Sciences. M. Burq states that during the epidemic of 1865-66 in France, only 1 out of every 1,270 workers in copper was attacked, the total number of individuals thus engaged being 37,000. With workers in iron and steel, on the other hand, 1 out of every 209 was attacked; and of those engaged on other metals than copper or iron, 1 out of 178.—*Lancet.*

NEW SOURCE OF CITRIC ACID.—From the *Journal de Pharmacie* we learn that Professor O. Silvestri, of the University of Catania, has recently discovered a great quantity of citric acid in the fruit of Cyphomandra betacea, a plant belonging to the Solanaceæ which is found scattered in the gardens of Sicily. Its natural habitat is Mexico; and it is also abundantly distributed in Peru and other parts of South America, where it is called *tomate de la par.* It is a woody plant, about 12 ft. in height, and from 1 to 1 5 per cent. of its fruit consists of pure citric acid. This acid has already been found by Bertagnini in the potato, and is probably present in greater or less quantity in all solanaceous plants.—*Lancet.*

LIME WATER IN BRIGHT'S DISEASE.—Kuchenmeister recommends in the treatment of Bright's disease and of nephrites after scarlatina the use of large doses of lime-water, theoretically from its having the property of dissolving proteine. *Lyon Médicale* details the treatment, and says that caustic lime in solution, or any of the soluble salts of lime, will answer equally well. He has seen the urine increase from 30 grammes to 120 the first day, 180 the second, 300 the third, and up to 1,020 the seventh day under this influence; sometimes a slight hæmorrhage necessitates the disuse of this treatment; but the quantity of albumen in the urine sensibly diminishes.

TAPPING OVARIAN TUMORS.—Dr G. Southam, of the Manchester Royal Infirmary, publishes in the *Lancet* a number of cases of ovarian tumor in which he obtained a favorable result by tapping. He says of the operation: "One or two tappings, especially when the cyst has obtained a considerable size, are usually succeeded by a marked improvement in the patient's health, and by a reduction of the original tumor, so that only a moderate incision through the abdominal parietes will be necessary for its extraction; both of which conditions are favorable to the success of the major operation.

"Amongst the cases of ovariotomy that have come under my notice, several have been those of patients in comparatively good health, where the tumors were of recent formation, of moderate size, and free from adhesions, and the operation itself, therefore, of the simplest description; but the results have not been so satisfactory as in cases of longer standing, and of a more complicated character,—acute peritonitis being usually the cause of death in the former, shock and its consequences in the latter. The tendency of the peritoneum, therefore, to inflammatory action seems to diminish with the duration of the disease, probably on account of the continued friction of this membrane against the surface of the cyst diminishing its sensitiveness.

"Accordingly, in the earlier stages of the disease, whether the tumor consisted of single or of multilocular cysts, it has for some time been my custom to advise a postponement of ovariotomy; tapping the tumor once or twice when it has become inconveniently large. Since adopting this plan, I have removed seven diseased ovaries, and in only one case was the operation fatal. Five of the patients had been tapped once, one twice, and one three times, the fatal case being among the first five. The recovery of those tapped only once was the most rapid, although in three of them the tumors were multilocular cysts. The two tapped more than once made favorable progress; but their complete restoration was not accomplished for several weeks, owing probably to the fluid in the cysts having become purulent after the second operation in one, and after the third in the other. Suppuration of the cyst I have not unfrequently found to be the consequence of repeated tappings; and, therefore, it is a matter of doubt whether the operation should be undertaken more than once or twice, as its repetition may diminish the chance of successful ovariotomy. The experience of Mr. Spencer Wells is also favorable to a preliminary tapping, for he found that, whilst the average mortality in 135 cases, where the patients had never been tapped, was 27.40 per cent., where the patients had been tapped once the mortality was only 25.64 per cent." —*Proceedings of the Royal Medical and Chirurgical Society*, 1869.

ACTION OF VERATRIN.—A very careful investigation of the therapeutic properties of veratrin has recently been made by M. Pégaitaz, who has published his results in the *Deutsches Archiv für Klinik Medicin* for October. He describes its effects both when taken internally and when subcutaneously injected; and finds them almost precisely the same, being as follows:—In the earlier stage excitation; subsequently depression. Then follow in succession, salivation, nausea, sensation of choking, vomiting, and usually diarrhœa. The voluntary movements become unsteady, the want of power displaying itself first in the posterior, and subsequently in the anterior, limbs; accompanying this there appeared to be a certain degree of stiffness. There were coincidently exaltation of the reflex sensibility and diminution of the sensibility. The temperature, the number of the respiratory acts, and of the beats of the heart, were all transiently diminished. Convulsions and tetanus finally set in; but careful examination failed to discover any indications of inflammatory mischief. Experiments made with a view of testing its applicability as a remedy which might be used hypodermically seem to have been unsatisfactory, showing that whilst it acts in this way similarly to its operation when given by the mouth, yet the injection produces very great pain.—*Lancet.*

DOUBLE VAGINA.—L. French, M.D., of Davenport, Iowa (*Am. Jour. Med. Sciences*), while attending a

married lady, aged 23, in her first labor, found on examination a double vagina. The septum appeared to be a fold or duplication of the mucous membrane, with a considerable quantity of cellular tissue intervening. It became evident that the septum must be cut, or left to rupture, as the child could not be born with parts in this condition. At this juncture a severe pain ruptured the septum, and labor was completed in a few moments. In five weeks but a trace of it was left along the posterior attachment like a cicatrix. Patient's recovery was rapid, and labia are now of equal size—while at first the left labium was larger than the right.

MEDICATED PENCILS.—M. Bonilhon, pharmacien (*Bull. Gén. de Thérap.*), remarks that the pencils of nitrate of silver, of tannin, and of various other substances, which are in ordinary use, are always too hard and too brittle. To remedy these defects, M. B. reduces the medicament to impalpable powder, and mixes it with an equal weight of melted gutta-percha; the mass, while hot, is rolled into the shape and size desired. On account of their elasticity they cannot be broken, and in every particular case they can be scraped to any desired point. They should occasionally be scraped, otherwise it may happen that the point contains so much gutta-percha, and so little of the medicament, that the crayon is practically inactive.

CONTINUOUS VENTILATION IN ACUTE EXANTHEMATA.—Dr. L. Kuglemann (*Deutsche Klinik*) treats his patients affected with either of the acute exanthems—scarlet fever, small-pox, measles, &c.,—with free ventilation; the doors and windows being left open, care being taken not to expose them to a direct current of air.

In the winter it is equally beneficial, especially when the temperature of the air of the patient's chamber ranges above from 12° to 14° R. Dr. K. has treated 5000 cases of measles, and 150 of scarlet fever, without the loss of a single patient, and without the occurrence of any secondary disease, or any serious complication.

SUCCESSFUL REMOVAL OF A CANCEROUS TESTICLE WEIGHING FIVE POUNDS.—A. J. Sawyer, M.D., Monroe, Mich. (*The Med. Investigator*), lately removed a cancerous testicle, weighing five pounds, from an Englishman, æt. 40, who received an injury to the right organ some five years since, by falling from a vehicle on to the shaft, while the horse was running. At the time of operating, there were two large openings in the tumor, situated upon and perforating the anterior aspect of the scrotum, the result of punctures with an exploring needle in the hands of one of his former physicians. The patient being anæsthetized, the first incision was made, beginning just below the external abdominal ring and extending down about 3 inches to near the right opening, passing through the envelopes of the spermatic cord and vessels. From the lower extremity of this, a semi-lunar incision was made on each side of the two openings—one of these openings was situated at about one inch below and to the right of the penis, and the other about one inch and a half to the right of the first, while both were located at about 8 inches from the lower extremity of the distended and diseased scrotum—of about 8 inches in length. That on the right of the operator was not carried at any point beyond the scrotal septum. The tumor was then dissected out, and *from* the median line carefully avoiding the *septum scroti*, the opposite testicle, the penis, and its connections with the body.

In order to reach the limits of the disease, the incision was extended through the inguinal canal to the internal abdominal ring, just below which the cord took on a healthy character, where it was ligated and the tumor removed. The loss of blood was very slight, the superficial perineal being the only artery that bled, and the only one ligated except the spermatic.

The wound being thoroughly cleansed and well washed with *arnica* and water, the lips were closed with divided sutures, except for a short distance at the lower and upper commissures of the wound, the former for the exit of blood, pus, etc., and the latter for the protrusion of the ligatures of the spermatic cord and artery, as well as for the discharge of the secretions. The whole was then covered with cloths saturated with *arnica* and cold water. Nothing else was ever applied, and in 7 days the wound was entirely closed, except where the ligature passed through, leaving a cicatrix 8 inches in length. The ligatures were removed on the 9th day; on the 14th the patient had his clothes on, and was fairly convalescent.

"MODIFIED LINEAR EXTRACTION" IN CATARACT.—Drs. H. D. Noyes, of New York, and E. Williams, of Cincinnati, have communicated two interesting papers on "Linear Extraction of Cataract" in the *Transactions of the American Ophthalmological Society*. Dr. Noyes is in favor of an incision of from five to five and a half lines (5‴ to 5½‴) in length. From four and a half to five (4½‴ to 5‴) lines is advocated by Dr. Williams, which accords with the views of V. Graffe. Dr. N. and Dr. W. make the middle of the incision as nearly as possible in the corneal margin; Prof. Knapp makes it in the sclerotic, at least half a millimetre (1-4‴) from the edge of the cornea. "From the point the cutting edge is the arc of a circle of 4 inches radius; at the summit of the arc the edge is prolonged backwards, parallel to the (straight) back, for a distance of four lines, making the distance from point to heel one and a quarter inches."

These knives are of two widths; the largest measures four millimetres, the smallest, three.

With reference to anæsthetics in the operation, Dr. Noyes employs *chloroform* to the extent of producing profound narcotism. Dr. E. Williams has given up anæsthetics altogether, "except in persons who have little or no self-control, or who refuse to make the trial."

Of 168 operations, according to this method—21 reported by Dr. Noyes, 47 by Dr. E. Williams, and 100 by Prof. Knapp—restoration of vision was perfect in 143, or 85 per cent.; partial in 15, or 9 per cent.; eye lost in 10, or 6 per cent.

Drs. Williams and Noyes advocate this measure over those previously employed.

GANGRENOUS STOMATITIS.—R. S. Anderson, M.D., of St. Louis (*The Med. Archives*), reports two fatal cases of gangrenous stomatitis, following measles, and alludes to three others which occurred in St. Louis. These cases are published on account of the variety of the disease, its extreme severity, its rapid progress, and its resistance to all the therapeutic means employed.

The disease is so rare that Dr. West states that he has only had the opportunity of witnessing it in 10 cases, in 8 of which the patients died. Rilliet and Barthez notice 21 cases, of which 20 died; and another French observer, M. Tourdes, has collected from different sources 239 cases, which, however, did not all occur in children, of which 176, or 75 per cent., terminated fatally. In the large majority of cases, measles is reported as the primary cause, though it has also followed typhoid fever, scarlatina, variola, and intermittent and remittent fevers.

THE BEST ANÆSTHETIC MIXTURE.—Dr. A. E. Sansom, of London (*Trans. Lond. Obstet. Soc.*), feels assured that the anæsthetic mixture to be recommended in obstetric practice should consist of one part of chloroform to two of absolute alcohol.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

OUR UNSUCCESSFUL CASES.

THE confession of sins, either of omission or commission, is so distasteful to poor weak human nature that there is always more or less of a disposition to dodge it. Even when our errors, from the circumstances of the case, are unavoidable, there is a natural dread of spreading them before the criticising review of our fellows. We are in general so impressed with our own imperfections and our many short-comings, that the temptations are too great for many of us to hide them, in the fear of risking what little reputation we may have for skill, good judgment, and perhaps even of common sense. Then, again, desire to appear in the best possible light not only prompts the premature reporting of successful cases, but causes too many of us to be indifferent as to their subsequent history, more especially if the death of the patient subsequently occurs as the direct result of the particular treatment. We quiet our consciences by all sorts of subterfuges, until in the end we too easily coax ourselves to forget our most important duty. This disposition is so generally appreciated by the profession at large, that all remarkable, sudden, and miraculous results are naturally looked on with suspicion, and lay the foundation of a ruinous distrust of each other. How often, with good reason, is it asked of certain individuals who make themselves more than ordinarily successful, "Is he trustworthy?" And how often must the reply be a negative!

The persons who are thus constantly violating the responsibilities which they owe to their profession, would have us believe that with them no accident or mistake can occur; that they, instead of being the humble instruments of scientific progress, are capable of making even science accommodate itself to any peculiar whim which they may have, and compelling it to violate every well-recognized law. It is pretty generally believed that the law of accident is a settled fact, and that the conditions must be fulfilled with as much precision as those of any other. The statistics of any particular operation cannot exceed a given ratio of successes; the calculations of careful and conscientious observers cannot and must not be overthrown because any aspirant for fame chooses to belie them by his own reported experience. We do not mean to be understood as saying that one individual cannot be more successful than another, but that his triumphs must not so far exceed the average of those equally skilful as to strike a candid investigator with astonishment. Again, an operator or a physician may be extremely fortunate for a time, but this is by no means an argument to prove that he must always be so. On the contrary, the balance in favor of the general average of successes will be struck in the long run, and the chances are quite certain that the number of cures, one after another, will in time be succeeded by a balancing number of failures, which generally follow each other with a given rate of rapidity. Those who have studied the subject affirm that there is not only a law of accidents, that is the more uniform in its workings as it is the more thoroughly investigated, but that certain sets of accidents occur epidemically—such, for instance, as railroad collisions, steamboat explosions, etc., etc.; and that when there is an immunity enjoyed for a longer period than ordinary, some terrible and extensive catastrophe supplies, in a given period, its due number of victims. That the working of the same law is evident in the average successes, failures, and mistakes in medicine and surgery, statistics unequivocally prove, and naturally throw a cloud of distrust over many an otherwise brilliant and extraordinary triumph.

No one can be proof against failure or mistake, any more than he can perform miracles. The best of us are constantly liable to err when, from the facts of a given case, it might appear the most improbable, and for which, in the majority of cases, we are in no wise to blame. But the greatest wrong we do to ourselves is in not being reasonably and conscientiously candid with each other. That we learn more by our failures and mistakes than we do by our successes, is a truism which no practical mind can gainsay, but, notwithstanding, we are constantly shrinking from our most important duties. The true scientific investigator must lose sight of self entirely; and his aim to arrive at the truth, and the truth only, must lead him to report his failures more frequently than his successes. All of us, in our investigations of disease, have difficult roads to follow—pathways that are strewn with pitfalls and sloughs; and those who have gone before owe it to us to point them out, that we may profit by their experience. Can we expect to gain anything if such facts are persistently held from us by the promptings of false pride and hypocrisy?

It must be admitted that the detailing of our mishaps is a trial of moral courage; but any one who is even ordinarily skilful always gains more by it than he loses in the estimation of his professional brother. If it be a clear case of oversight, the sympathies of his listeners are always with him; and if distrusts of skill arise in their minds, they are at once more than replaced by esteem for him as a candid, modest, and determined ob-

server. It is only such as feel that they have something in them for good, that have studied well and patiently the cases that have been presented to them, and that have a single desire to arrive at the truth for the truth's sake, that can afford to recite their failures, and when called to the diagnosis of a doubtful case can defiantly say, "I do not know." Show us a man who thinks he can never make a mistake in diagnosis, and we will show you one who is not much addicted to making post-mortem examinations.

Every one who has been any time engaged in practice, knows by painful personal experience how impossible it is to be infallible; how often the judgment is in error; how often the very senses are apt to deceive us; how often we drift into what are afterwards found to be unwarrantable conjectures, and how many sins of omission as well as commission we find we have been guilty of, when, alas! it is too late to undo them. It is natural to assume that the vast majority of these experiences are seldom if ever made to benefit more than one individual, who makes himself doubly the sinner by refusing an item of experience which might, in similar cases, not only mitigate much suffering, but actually be the means of saving life. When such considerations as these come up, is the self-love of the sinner, his desire to maintain what he considers his fair fame, or is even the wish to escape ridicule, sufficient to excuse his silence?

It is pleasant to note the desire for mutual improvement throughout the medical profession of the country manifest in a determination to maintain the healthful action of the State Societies. Every State, with a few exceptions, has a medical organization which is in a prosperous condition. Not the least among these is the youthful and vigorous State Society of Iowa, which held its second annual meeting the first of last month at St. Paul, Minn. Its proceedings were characterized by the purest of motives to elevate the profession and enforce the code of ethics of the American Medical Association. Our Western brethren are in earnest in reference to their opposition to quackery in every shape, and if they continue as they have begun, and the members govern their actions in accordance with their principles, many older and more influential societies in the East will be left in the background. Dr. Samue Willey, of Saint Paul, has been re-elected President, an honor to which his position as a leading practitioner of the State, and his special exertions in bringing the Society into existence, justly entitles him.

Inasmuch as the subject of Relapsing Fever is at present claiming so much attention, we have endeavored to supply the demand for information on the subject by the publication of a lecture by Prof. A. Clark, and one by Prof. A. L. Loomis, both of which will, we trust, be read with interest and profit.

Reviews and Notices of Books.

Moral, Intellectual, and Physical Culture; or The Philosophy of True Living. By Professor G. Welch, of the Department of Physical Culture, Yale College. New York: Wood & Holbrook. 1869.

The principal fault we have to find with this book is, that it contains a little of almost everything. The author has attempted too much. That portion of the work devoted to gymnastics is full and instructive, though very like what Dr. Dio Lewis has long taught. In the treatment of moral and intellectual culture, Dr. Welch is evidently out of his depth; so he contents himself with stringing together a host of well-worn axioms and scriptural quotations, that can be as well found elsewhere. The remarks on diet, bathing, exercise, &c., show considerable ignorance of hygiene, and are often calculated to mislead the credulous, though the intentions of the writer are doubtless good. Some of the statistics are interesting, and many old facts are presented in a new and attractive garb. Altogether, as a medley of gymnastics and religion, physiology and morals, poetry, rhyme, and old proverbs, this elegant little volume is probably without a rival in the English language.

The Intermarriage of Relations and the Laws of Human Increase. By Nathan Allen, M.D.

Dr. Allen is one of the few in the profession who make it their duty and their pleasure to call the public attention to the important themes of science.

The essay of Dr. Allen on *The Law of Human Increase* has already been made familar to the profession and to the people, and has attracted something of the attention that it deserved. The paper on the Intermarriage of Relations, which is a continuation of the same subject, and really a part of it, discusses an important question concerning which there is now an honest difference of opinion among men of science. Without entering into detail, we may say in general that on this subject we agree substantially with the *Journal of Medical Science*, that the intermarriage of cousins by no means necessarily tends to degeneracy, and that their offspring may, in some cases, be all the sturdier for the relationship of their parents. Our creed on this subject, compactly stated, is this: Children take their qualities, good and bad, from both parents and their ancestors. Qualities which are common to both parents are twice as liable to be inherited as those which exist only in one parent. In hereditary descent evil qualities are more potent for evil than good qualities are for good, just as a little sediment easily renders a clear and pure mass of water turbid and foul. Blood relations are more liable to have qualities in common, either good or bad, than those who are not blood relations; and as evil qualities are more potent for evil than good qualities are for good (one bad diathesis being sufficient to vitiate and destroy all other elements of character in a family), therefore the immediate, or more usually the remote, offspring of blood relations are more likely to be inferior in descent than the offspring of parents who are not blood relations. But the evil consequences of the intermarriage of cousins are not such as to justify any prohibitory legislation.

Concerning the Law of Human Increase propounded by Dr. Allen, we desire to present the following queries:

1. Is it desirable that population should increase with rapidity? Dr. Allen seems to assume that it is. Is a community or nation where there are *eight* children in a family necessarily more happy, more prosperous, and

more wise than a community or nation where there are *two* children in a family? Not population, but righteousness exalteth a nation. Is it not a fact of comparative physiology that the productiveness of organized structures increases inversely with the complexity of organization; that those millions lowest in the scale are millions and millions of times more productive than man, who is highest of all; that between the most intellectual of mankind and the lowest and simplest forms of animal life, there is a gradation of productiveness which, with irregularities that can be explained, corresponds to the complexity of structure? The lowest types multiply by millions. A single *frustule* of the *Diatomacea* produces 1,000,000,000 in one month; the *Gonium*, 268,435,456 in a week; a *Paramecium*, 268,000,000 in a month; a species of animalcule, 170,000,000,000 in four days. Types which are higher multiply only by millions, and thousands, and hundreds. Fish are very prolific, though less so than the still lower types. The cod spawns a million at once; many fish spawn by thousands. Types that are higher still breed by tens. The annual production of the partridge is 10 or 15; of the grouse, 10; of the pheasant, 10; of the small rodents, 10 at a birth. The rate of multiplication of the domestic animals is well known. Man produces slowly, and after many years of preparation. Intellectual men—the very highest orders of the human race—are notoriously unprolific. The comparative estimate is variously modified by external conditions and by activity, but in the average the law holds. The subject in all its bearings is ably discussed by Herbert Spencer in the last chapter of his Principles of Biology.

We hold that the civilization of the future will be less prolific than that of the present; but that the quality will, a thousandfold, compensate for quantity. It was said of Dr. Chalmers, "he was not one man, he was a thousand men." Better one child well trained to virtue and raised to usefulness than a million neglected into misery and starved into crime. The curse of England to-day is the 12,000,000 of her wretchedly poor, who rise in the morning not knowing where they will get their breakfast. We hold that every child born to such parentage is an unnecessary and lamentable addition to the world's sin and sorrow.

2. Is it true that a proper balance of temperaments is the great cause for fertility? Consider the wondrous fertility of the Irish and English peasantry. Are their temperaments well balanced? Herded in sensuality, grovelling in ignorance, darkened by despair, bruised and crushed by social prejudice, their brains coarsely organized, poor in quality, fallow, idle, muddy as the bogs in which they live, oppressed by superstition, which, after all, is the chief feature that helps to raise them but a little above the swine droves, by whose side they promiscuously sleep—are these drunken animals, with just force enough to breed, well-balanced temperaments? No; fertility is a vast and complicated theme. It depends not on one or two, but on a wide and diverse range of factors—diet, air, climate, education, race, special temperament, and the relation of temperament, occupation, social influence, and means of subsistence.

3. Is it desirable that the human temperaments should be well balanced? Is harmonious development the end of existence? Dr. Allen assumes that it is, and the general voice of intelligent mankind would theoretically agree with him; and yet we contend that the question is an open one at least. Is not the highest culture of the brain, with all the rest of the body in subjection to, and subordinate to it, preferable to an even culture of the whole man? Are not Virgil, Raphael, Shakspeare, Pascal, Edwards, Schiller—all of whom cultivated the nervous temperament at the expense of the muscular, the sanguine, and the lymphatic—of more value to the world than thousands of properly balanced temperaments?

Is not a scientific cause more weakened than strengthened by appeal to the authority of the Bible? There is not a scientific theory, fact, or principle, that has been originated, elucidated, or fortified by any appeal to the Scripture, considered as a divine revelation; on the contrary, all the sciences have been retarded, hampered, perverted, by the attempts that have been made either to sustain or refute them by reference to the Bible as an authority in science. Suggestive and interesting *illustrations* of scientific truths may indeed be drawn from Scripture, but all attempts to build up or sustain any scientific theory by scriptural *arguments* must re-act injuriously not only on science, but also on religion itself. Between Genesis and Revelation, we find no light on the difficult and complex subject of human increase, nor on any other question of physiology or hygiene; and any arguments wrought out of interpretations of Scripture as a guide in science, either for or against scientific theories, will not stand for a moment among the scientific leaders of the present generation.

In conclusion, we cannot speak too warmly in praise of the efforts that Dr. Allen has so successfully made to enlist the public interest in this vast and important theme. It is because we do thus highly appreciate his very able and interesting pamphlet, that we have preferred, in the interests of science, to indicate wherein his argument appeared to us deficient or untrue, than to refer to the many points with which we are in perfect accord, and which we could unreservedly praise. The problem of population, in its broadest range, includes all other social problems,—the relation of the sexes, the status of woman, labor and capital, &c., &c.,—and he who solves it will solve the problem of existence.

MANUAL OF HYPODERMIC MEDICATION. By ROBERTS BARTHOLOW, A.M., M.D., Professor Mat. Medica, &c. 12mo, pp. 150. Philadelphia: J. B. Lippincott & Co. 1869.

THE author of several prize essays, upon subjects demanding an extensive acquaintance with new remedies, appears before us once more in a neat and interesting little volume, full of historical, technological, and therapeutical instruction, in relation to the instruments and methods used in the hypodermic administration of medicines. The principal agents utilized in this manner are treated of, more or less at length, in fifteen chapters, which form the second part of the volume. Those devoted to Morphia, Atropia, and Strychnia are particularly worthy of mention. Woorara, Nicotia, Physostigma, Caffein, and Ergotin appear as subjects of others. Each of these chapters opens with a description of the solution and dose, and contains a statement of the physiological effects and medical uses of the remedy under consideration.

The whole is enriched with many practical suggestions, and some carefully conducted experiments upon the human subject.

The book is well worth a careful perusal.

THE LIVERPOOL MEDICAL AND SURGICAL REPORTS. Vol. III. Edited by Drs. P. M. BRAIDWOOD and REGINALD HARRISON. London: John Churchill & Sons. 1869.

THE aim of this journal is to present, in an interesting form, all the valuable medical information that can be collected in Liverpool and vicinity. The present volume contains fifteen original articles by gentlemen well known in the profession, including Drs. Wollaston, Harrison, Bickersteth, Lyster, and Braidwood. The

latter gentleman contributes his views on the treatment of croup and diphtheria, with statistics regarding tracheotomy. A chapter on sea-sickness, by Dr. De Zouche, enters thoroughly into the pathology and rational treatment of that malady. A large number of cases appropriate to the subjects discussed are recorded in the Reports.

BELLEVUE AND CHARITY HOSPITAL REPORTS. D. Appleton & Co. 1870.

THE Reports of our metropolitan hospitals, affording, as they do, a vast field for clinical observation, are destined to fill an important place in the medical literature of the future. We had expected to see in the first volume of Bellevue Reports something more imposing than the volume before us; something that would compare more favorably with the elaborate reports issuing from the London hospitals. The volume opens with a brief historical sketch of Bellevue Hospital, and some notice of its founders and early patrons. The first article, on procidentia uteri, is contributed by Prof. Taylor, and contains much regarding amputation of the cervix, and the views of Huguier, that sounds familiar. The cases, however, are of decided interest. Austin Flint, Sr., contributes his opinions on the diagnosis of pulmonary and cardiac diseases, and gives an analysis of one hundred and two cases of Bright's disease. Dr. Sayre gives the results of his experience in fractured clavicle, and in diseases of the ankle-joint. Dr. Hamilton is the author of an article on Hernia, with seventy-three cases. Dr. Metcalfe furnishes a compilation of amputations, performed at Bellevue. Dr. Hammond gives his views and experience on the effects of intellectual exertion, and Dr. Thomas contributes the history of nine cases of ovariotomy. The report of the Pathological department, by Drs. Southack, Janeway, and Delafield, is highly interesting, and the classification adopted seems excellent. We find nothing whatever on obstetrics; and while the Reports are good as far as they go, we cannot regard them as particularly creditable, in quantity or variety, to institutions possessing extraordinary clinical advantages, and looked upon as the leading hospitals of the country.

OBSTETRIC APHORISMS. By JOSEPH G. SWAYNE, M.D., of Bristol. From the fourth English edition. Edited by E. R. HUTCHINS, M.D. Philadelphia: Henry C. Lea. 1870.

THE object of this little manual is to furnish, in small compass, such practical directions for the management of ordinary and extraordinary cases of labor as may be acceptable to the young practitioner, and to point out more particularly the emergencies in which assistance should be sought. It contains many useful hints regarding the care of both mother and infant, and well deserves the popularity it has attained.

A PRACTICAL TREATISE ON THE DISEASES OF CHILDREN, by ALFRED VOGEL, M.D., Prof. Clinical Medicine in the University of Dorpat, Russia. Translated and Edited by H. RAPHAEL, M.D., late House Surgeon to Bellevue Hospital, etc. From the fourth German Edition. Illustrated with six lithographic plates. New York: D. Appleton & Co. 1870. 8vo, pp. 603.

THE work before us, for the first time in an English dress, comes with the endorsement of a fourth edition in German, and a translation into three other languages. Very little more need be said in its recommendation, except perhaps to refer to the very acceptable manner in which Dr. Raphael has discharged his duties. The work, as a whole, is a clinical record of the more common diseases of children, by a most careful, conscientious, and painstaking observer. The descriptions of the symptoms of the different maladies, from the most trivial to the most important, are very minute, accurate, and intelligible, while the therapeutics are carefully discussed. The remedies advised are few, and are only such as the experience of the Author has led him to endorse as really serviceable. The pathology is fully up to that of the German school, which is saying everything for its thoroughness and accuracy. To convey some idea of the practical character of the work, we select at random the following:

"*The Signification of a Coated Tongue in Children.*—It is necessary, first of all, to state that most nurslings, in the first weeks of life, have a white coated tongue, along with which they do not display the least digestive disturbance. Aside from that, the tongue becomes coated in most of the gastric and intestinal affections of small children, and probably only in consequence thereof does the appetite decrease. A thickly furred tongue is but seldom met with in children; as a rule, a white flush only is observed, but this may exist for a long time after the appetite has returned, and may just as well be produced by local diseases of the mouth, thrush, stomatitis catarrhalis, diphtheria, injuries, chemical irritants, and burns, as by disease of the stomach or bowels. There are also permanent, or at least of several months' duration, partially coated tongues, which possess no influence whatever upon the continuation of good health. A special name has even been invented for this condition, *pityriasis linguæ*. It consists of white islands, or circles or semicircles, the rest of the tongue being of a nominal rose-red tint; these spots are entirely indebted for their origin to an accumulation of epithelium-scales. In atrophic children, transverse fissures are often seen upon a very smooth, red tongue; the fissures display yellow bases, obstinately resist the cauterizing treatment, and do not disappear before death. The furred tongue of measles, scarlatina, typhus fever, etc., has the same significance in older children as in adults, and will be specially described with every individual affection."

We might select other remarks equally to the point and equally practical, but one must answer for the whole, and we will content ourselves by giving the reader the general plan of the work, with the recommendation that he examine into details himself. First in the natural order are the introductory remarks relating to the peculiarities of the child, in an anatomico-pathological point of view, particularly with reference to the respiration and circulation, the secretions and growth. The general rules for the examination of children, which follow, are plain and to the point, which may also be said of those for the nursing and care of children, comprising Chapter III. The second part of the treatise is devoted to special subjects: 1. To those diseases the direct result of delivery. 2. To those of the digestive, circulatory, and respiratory apparatus; to those of the nervous system, of the urinary organs, skin, and secretions in general. Six beautifully executed lithographic plates, illustrating the text, add much to the value of the work, aside from its elegant typographical execution. The profession of this country are under many obligations to Dr. Raphael for bringing, as he has done, this truly valuable work to their notice, and placing it within the reach of every one not able to read the original.

ON THE WASTING DISEASES OF INFANTS AND CHILDREN. By EUSTACE SMITH, M.D., London. Phila.: Henry C. Lea. 1870. 1 vol. 8vo, pp. 195.

THE name of "Smith" seems to be an authority on the treatment and knowledge of the diseases of children.

Last year we had the pleasure of scanning, for the first

time, the pages of a work entitled, "A Practical Treatise on the Diseases of Children," written by J. Lewis Smith, M.D., of our own country, regarded as one of the best text-books on this subject.

The work now before us, beautifully written and arranged by the London teacher, which has been published in parts in the *Medical News and Library* during the past year, treats of those subjects which are not sufficiently dwelt upon by our American and foreign writers in their extended monographs on the ailments of the young. In fact the author states in the preface that he "had not long begun the study of children's diseases before he found that even the best systematic treatise dealt but imperfectly with the clinical condition of chronic wasting, and did not consider together the various disorders to which it may be due." It is offered as a contribution to the literature of the diseases of children, in the hope that the practitioner may have some practical guide in the management of this fatal condition. Dr. S. is on the right track, and deserves praise for this contribution, which helps to fill the blank now existing in the clinical knowledge of diseases occurring among the little folk.

The book opens with an introduction, and is divided into *nine chapters*, which treat of "Simple Atrophy from Insufficient Nourishment," "Chronic Diarrhœa," "Chronic Vomiting," "Rickets," "Congenital Syphilis," "Worms," "Chronic Tuberculosis," "Chronic Pulmonary Phthisis," and "Tuberculization of Glands." The subjects treated in the last five chapters cannot be equalled in any work previously written on this branch, and should be read by every physician who wishes to learn all that is worth knowing concerning the *wasting diseases* of children.

THE PHYSICIAN'S HAND-BOOK for 1870. By Drs. WM. ELMER and ALBERT D. ELMER. New York: W. A. Townsend & Adams, Publishers. pp. 287.

THIS handy and compact pocket manual for the medical practitioner is so well known that it requires no laudation from our hands. It opens with a full "Index to Diseases," classified according to the latest authorities, with every known symptom. This portion, occupying the first 48 pages, with the "List of Incompatibles" and "Remedial Agents," is very complete, and is a valuable aid to the medical man in the way of refreshing the memory in materia medica and therapeutics.

The "Diagnostic Examination of the Urine" contains very complete and practical directions for the examination of this important secretion. We should like to see similar directions in other pocket companions.

The remaining pages are devoted to the Calendar for 1870, Names and Addresses, Bills and Accounts, Record of Practice and Treatment, Table of Signs for Daily Practice, Obstetric Record, Diagnostic Record, Obstetrical Calendar, and General Memoranda.

The physician will hardly find a more complete and useful diary than this one just issued by this enterprising publishing house.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA AT ITS TWENTIETH ANNUAL SESSION, HELD AT ERIE, JUNE, 1869. Fifth Series. Part II. Paper, pp. 305.

THE Medical Society of the State of Pennsylvania met in the Court-house at Erie, June 9, 1869, Dr. John Curwen, of Dauphin County, President, in the chair, supported by Vice-Presidents Drs. W. M. Wallace, of Erie, and P. D. Breinig, of Northampton.

DR. GEO. C. BENNETT, of Erie, in welcoming the delegates, stated that it was less than a quarter of a century since the Society first met in convention, and only *two* of the original members were present.

The address of the President on "Mental Disorders" and their management will well pay perusing, and those forms of insanity called "Bell's Disease," or, by English writers, "typhomania," "folie circulaire," described clearly and accurately by Dr. Isaac Ray, and "general paresis," are minutely referred to, and he wishes to impress upon his medical confrères the importance of early treatment in the first stages of all mental disorders.

In the report of the Committee on "Intemperance as a Disease," Dr. Joseph Parrish, chairman, it is stated that from 30 to 50 per cent. of cases of habitual alcoholic intoxication are curable, and they make the additional statement that 90 per cent. of opium cases are recoverable under institution treatment.

PROF. GROSS, M.D., LL.D., presented an able report "On the Training of Nurses," which will be sent to the State Medical Societies of the different States of the Union, inviting their coöperation in the establishment of schools for the training of nurses for hospitals and private families in accordance with the principles therein advocated. A novel case of *longitudinal rupture of the uterus*, involving the whole texture of the organ, was reported by J. McConaughy, M.D. This was the only case he had the misfortune to meet with in a practice of over thirty years, and the only one that has happened in Westmoreland County, Pa. The "Report on Use of Stimulants by the Profession," read by Dr. H. Corson, chairman, takes strong ground against the indiscriminate employment of alcoholic liquors in disease. In regard to the employment of whiskey as a cure and preventive of consumption, let the report speak for itself: "There is scarcely a single person in the whole country threatened with or suffering from that disease who is not dosed daily with either brandy or whiskey, in large doses, by advice of the physician, who conscientiously regards them as the great remedies to increase vital force, and thus avert the disposition to tubercle. From most careful observations made in a large region of country, when the history of every case of phthisis could be ascertained from week to week, we have failed to discover the least benefit derived from the use of alcohol, either as a preventive or remedy in that affection."

The remaining portion of the "Transactions" is taken up with the county reports on the prevailing diseases of each section of the State, mortality, etc., etc.

The list of *permanent members*, thirty-four in number, and the *code of ethics*, are also appended.

Philadelphia is the place for holding the meeting in 1870, and W. M. Wallace, M.D., of Erie County, will preside on that occasion.

LOSS OF WEIGHT BY STARVATION.—Dr. Nicholson, of Portland prison, England, mentions a case where a convict starved himself voluntarily for some days. On the sixth day of absolute starvation he had lost 7 lbs., having weighed at first 107½ lbs., and thus falling to 100½ lbs. The heart sounds were faint, and the pulse soft and low. The urine very acid. No albumen. On the 10th day he took all the diet allowed, and regained his original weight on the 13th day.—*Med. Press and Circular.*

BELLADONNA IN WHOOPING-COUGH.—Dr. Wordsworth, of England, thinks that the disease can be "greatly cut short" by giving the extract of belladonna in increasing doses, until the pupils remain widely dilated.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, JAN. 26, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

MISCELLANEOUS SPECIMENS.

DR. FINNELL exhibited some fragments of gall-stone removed from a gentleman eighty years of age, who died of fatty heart; he likewise presented a specimen of perforating ulcer of the duodenum from a patient fifty years of age, who was found on the street vomiting blood. The stomach as well as the duodenum contained large clots. The perforation was the diameter of a goose-quill. There were evidences of peritonitis in the neighborhood. A third specimen was one of epithelial cancer of the lower lip, extending from the commissure to two lines beyond the median line, removed by operation; and the fourth was a specimen of cancer of the omentum in a hog.

FRACTURE OF OUTER PORTION OF HEAD OF RADIUS.

DR. MASON exhibited first a rare specimen of fracture of the outer portion of head of the radius, removed from a dissecting-room subject. In looking over the literature of the subject, he had found but two similar instances mentioned by Hamilton in his work on fractures, which were in Mütter's cabinet, and one by Dr. Gross, also met with in a dissecting-room subject.

REMOVAL OF SUPERIOR MAXILLA.

A second specimen was the entire right superior maxillary bone, removed by operation from a patient aged 20, in the Colored Home Hospital. He had been perfectly healthy until the summer of '68, when he commenced to have a pain in the molar region of the right upper jaw, which was soon after followed by a tumor in that locality. Subsequently the teeth in the neighborhood were removed, but the growth continued to increase steadily until the time of the operation. The usual incision was made, when it was discovered that the orbital plate was involved. The periosteum was separated from this portion as far back as the spheno-maxillary fissure, a chain saw passed through the same, and the whole mass was without difficulty removed. The patient at last accounts was doing well. The tumor had been examined by several gentlemen, who declared it to be myeloid in character.

HAIR-PIN IN TRACHEA—EMPHYSEMA, ŒDEMA GLOTTIDIS, TRACHEOTOMY AND DEATH.

A third specimen exhibited by the same gentleman was a hair-pin removed from the trachea of a child seventeen months old. It had been accidentally swallowed by the patient while at play. Dr. Mason saw the case about an hour after the accident, and after a great number of unsuccessful attempts had been made to extract the foreign body. Passing the finger down the œsophagus, about ¼ of an inch of one of the prongs was reached. After anæsthetizing the patient, the pin was with some difficulty removed by the œsophageal forceps. The throat was discovered much swollen, and there were marked evidences of emphysema, giving rise to the suspicion of a laceration of the trachea. This, however, could not be positively determined by any digital examination made at the time. After the operation the child seemed quite comfortable, and Dr. Reynolds, the partner of Dr. Thebaud, in the absence of the latter gentleman, whose patient it was, watched with the case. In the course of an hour afterwards, Dr. Reynolds sent for Dr. Mason to perform tracheotomy, as the patient, from the extension of the emphysema (which at that time had reached as far as the navel on the left side), and the consequent increase of the suffocative symptoms, was in danger of dying. Everything was made ready for the operation with the greatest despatch, but just as it was about to be commenced the lips resumed their natural hue and the urgency of the symptoms passed off. Shortly after Dr. Thebaud arrived, and while talking over the case the alarming symptoms again showed themselves, when that gentleman performed the operation at once. The patient passed a very comfortable night, the emphysema began to disappear, and everything promised well. About ten o'clock the following morning an urgent message was received by Dr. Mason to the effect that the child was in convulsions. These latter continued at intervals until death took place, shortly after twelve.

No autopsy was allowed. An examination of the throat was made by the finger, the jaw being firmly depressed, but no laceration of the trachea could be discovered, although without doubt such a condition of things existed. Extensive œdema glottidis was very evident.

In conclusion, he remarked that two large veins, the size of crow-quills, were found traversing the field of the operation, and recollecting an accident that had happened to Dr. Sands when the same condition of things had existed, at his (Dr. Mason's) suggestion these were both tied with a double ligature before being divided, with the result, no doubt, of preventing instant death by the entrance of air into the circulation.

DR. SAYRE expressed his regret that no autopsy could be obtained, and suggested the propriety of turning such cases over to the coroner, who would compel the necessary examination.

DR. SANDS was of the opinion that the law required only the assertion from the physician as to most probable cause of death.

DR. FINNELL thought that the only justification for such a procedure in the given case was a reasonable doubt as to how the hair-pin gained its entrance into the throat.

INFLAMMATION OF APPENDIX VERMIFORMIS—RUPTURE CAUSED BY OVER-EXERTION.

DR. EAGER exhibited an appendix vermiformis with perforation, removed from a single gentleman, thirty years of age, a native of Massachusetts, and a merchant of this city. At the second battle of Bull Run, in 1862, while serving as an officer in the army, he received three flesh wounds in different parts of his body, besides being struck with a flattened spent ball in the right iliac region. This latter occasioned him at the time more pain and inconvenience than all the rest, although at the point of injury nothing more than a slight scratch was discoverable. His neighboring clothing was, however, torn, showing that the missile must have come with considerable force. So much was he disabled by the latter bruise that he could not get himself from the field, and, after remaining there for the better part of two days, was duly exchanged.

He shortly after regained his usual health, and enjoyed it until the fifth of last December. He went to church twice on that day, ate a hearty dinner, and spent the evening with some bachelor friend, returning home about half-past ten. About two o'clock the following morning he awoke with intense pain in his bowels. His fellow-boarders, being called, plied him with the usual domestic remedies, but with little benefit. Towards daylight he vomited once. This

was the only time during the whole sickness that this symptom showed itself.

The patient, residing in the same house with Dr. Burke, was seen by that gentleman, who prescribed for him various remedies, among which were leeches. These latter the patient was not at first inclined to have applied, until the urgency of his symptoms in the evening compelled the doctor to insist upon it. When Dr. Burke first saw the patient the pulse was 104, and there was complaint of intense pain at a point on the abdomen two inches in diameter, just above Poupart's ligament. Following the leeches were hot fomentations, with a grain of opium every two hours.

Dr. Eager saw the patient about noon on Tuesday. The pulse was then 108; there was intense thirst, the skin was moist, and there was no tympanitis, neither was there any tenderness until the spot previously indicated was reached, when pressure gave rise to exquisite pain. No position would give him any ease. The quantity of opium was increased, and oiled silk was added to the fomentations. When Dr. E. saw him again in the evening, he seemed a good deal relieved from pain, although his pulse remained considerably above 100. His respirations had decreased from 36 in the morning to 24. He slept, perhaps, half the night.

On Wednesday morning about eleven o'clock his pulse was 96, and respiration 15, in which condition he continued until nine in the evening, his mind remaining perfectly clear, there being no evidences of peritonitis, and the point of tenderness not being as painful as before. At this time, without having previously had any trouble with his water, he was seized with a desire to urinate, and for that purpose arose and made several unsuccessful attempts to relieve himself. At eleven o'clock Dr. Burke catheterized him, and drew off eight ounces of dark-colored urine. At three o'clock the following day, the patient was rather suddenly seized with tenderness and intense pain over two-thirds of the abdomen. Dr. Eager was immediately sent for, and arrived at four, when Dr. Parker was called in consultation at five. There was no tympanitis at this time, neither was there any throughout the whole progress of the case. The patient was examined carefully, with a view of ascertaining if there was any abscess forming. No evidence of such a condition could be found, and it was rather a question whether or no the appendix was involved in the peritonitis, which, by the way, was then very evident.

He went on rapidly getting worse, and finally died on Saturday morning at five o'clock.

The autopsy was made thirty hours after death by Dr. Mason. On opening the abdominal cavity there were evidences of intense peritonitis; everywhere the peritonæum was intensely injected, and the intestines were firmly and extensively glued together by adhesions. Large patches of lymph were seen in many places, and some of these equalled in thickness the breadth of the little finger. The parts were carefully raised, and the appendix was easily discovered attached to the abdominal walls of the right iliac fossa; and to avoid tearing, Dr. Mason dissected the peritonæum covering the parietes sufficiently far to enable him, after tying the appendix, to remove the whole specimen uninjured. The process was an unusually long one, and about its middle was an enlargement twice the diameter of the organ at any other point; and just above this bulging portion, and near the gut, was the point of perforation. From the distension six small bodies were removed, resembling in shape and appearance ordinary mouse-dung.

In conclusion Dr. Eager remarked that this perforation, in all probability, did not occur until such time as the patient left his bed, and exerted himself to pass his water. If that were true, a practical lesson could be drawn, never to allow the least exertion on the part of a patient while suffering from inflammation of that particular organ.

INFLAMMATION OF APPENDIX WITHOUT PERFORATION.

Dr. Flint commended the suggestion of Dr. Eager to the consideration of the members. He believed he had seen a case of inflammation of the appendix that had not been attended with perforation, and he did not think that similar ones were very infrequent. "The late Dr. Jackson of Boston has described an affection, obscure to him, as he said, which had all the symptoms of inflammation of the appendix, characterized by localized peritonitis and pain. I know it is customary to attribute the local disease to any little matter that may be found in the appendix, but it seems to me often without much grounds."

THE FATAL ATTACK OF PERFORATION OF APPENDIX GENERALLY PRECEDED BY PREVIOUS INFLAMMATION.

Dr. Jacobi was of the opinion, from what he had seen, that most if not all of those cases of inflammation of the appendix, when first discovered, were not of recent origin, but that one or more antedated the fatal attack. These previous attacks were liable, by adhesions and the like, to distend the process, and render the escape into its cavity of irritating substances possible. If this were not the case, perforation would of necessity be exceedingly common.

Dr. Thomson referred to a case in point that followed an attack of pelvic cellulitis five years before.

Dr. Eager remarked that he had been called to see a case, on the previous Monday, of a gentleman who had all the symptoms of localized inflammation in the right iliac region, and which to his mind were clearly those of peri-typhilitis. He had also met with two others similar to those referred to by Dr. Flint, one recovering after five, and the other after seven weeks' confinement.

Dr. John C. Peters recollected the case of a lad fifteen or sixteen years of age, who had had repeated attacks of inflammation of the appendix, in the last of which rupture occurred as the result of getting out of bed.

CALCAREOUS DEGENERATION OF OVARY.

Dr. Sands exhibited a specimen of tumor of the ovary, on behalf of Dr. W. J. Almon, of Halifax, with the following note of description from that gentleman:

"I send a specimen of bony degeneration of the ovary, which, if you think of sufficient interest, you may exhibit to the Pathological Society. The brief history of the case is this: The patient was an unmarried woman of about fifty-eight years, and had for the last thirty years suffered more or less from spinal irritation, and for the last six years had complained of a constant numbness in the muscles of the left thigh. About three years ago, she called my attention to a tumor in the left iliac region, which could only be perceived at times. It was about three inches long by one broad, and lobulated. She complained at this time, and to the time of her death, of great pain in walking, nausea, and a feeling of distension in the abdominal region. About forty-eight hours before her death, as she had just left the night-chair, her sister (who, a few minutes previously, had given her an injection) heard a loud snap, and asked what that was? She replied, 'Did you hear it too? I thought a pistol had gone off within me.' I was sent for about an hour after, and found her suffering violent pain in the abdomen, increased on pressure, cold hands and feet, with a small and feeble pulse. Symptoms indicating rupture of the intestine.

"On making a post-mortem examination, assisted by Dr. Tupper, we found a rupture of the small intestine near the tumor which had been perceived during life, and which was an enlarged mesenteric gland attached to the intestine. All the other mesenteric glands were enlarged and indurated. On passing my hand into the true pelvis, I found it filled with a hard, ponderous tumor, which was the ovary, that had undergone a bony degeneration. As I have not met with a case like this, either in my practice or reading, let me know what you think of it."

Dr. Sands remarked that the tumor was a very solid mass, lobulated externally, and had the consistency of bone. When he saw it first he thought the doctor's opinion was correct—that it might be bone. Dr. Sabine had examined it, however, microscopically, and failed to find anything but a calcareous degeneration. He accordingly supposed it to be an ovarian cyst which had undergone such change, this being not a very uncommon occurrence. He had found no mention of any case of osseous degeneration of such growths, although Virchow speaks of cartilaginous degenerations. These latter were exceedingly rare.

CALCULUS OF CYSTINE, ETC.

Dr. Post exhibited the skull of a Flathead Indian of the Quinault tribe, also one of a dissecting-room subject, which was worm-eaten over its superior surface, and perforated at several points at its base. This condition was presumed to be the result of syphilis. He also exhibited a beautiful calculus, composed entirely of cystine. It was two-and-a-quarter inches in length, two-and-an-eighth inches in breadth, and two inches in thickness.

CALCULUS OF SUBLINGUAL DUCT, ETC.

Dr. Sayre exhibited a very minute pointed calculus, which, by obstructing the sublingual duct of a young lady, had caused her to be in imminent danger of choking. It was removed without difficulty, and with immediate relief to the symptoms. He thought it possible that the hair of a tooth-brush had been engaged at some time in the duct and formed the nucleus of a calcareous deposit.

Dr. Watts thought that it might be a small fish-bone.

On motion it was referred to the Committee on Microscopy.

MORBUS COXARIUS.

Dr. Sayre presented the neck and trochanter major of the femur, removed by operation from a patient twenty-five years of age, who had been first attacked with symptoms of coxitis in 1862, while engaged in digging a well. The disease took the usual course until the third stage, during which period he was admitted to the Bellevue Hospital. The acetabulum was found eburnated, and between it and the caput femoris was a pulpy material, which accounted for an absence of crepitus during life.

SINUOUS ABSCESS OF METATARSAL—NECROSIS OF SKULL CAUSING CHOREA, ETC.

Dr. Pooley presented a fine specimen of sinuous abscess of the metatarsal bone of the great toe, removed by operation from a girl eleven years old. The periosteum was of course left.

Another specimen was a portion of necrosed skull, the result of injury, likewise removed before death from a girl eight or nine years of age, who since the accident had constant attacks of chorea. Finally, a baggy swelling of the part occurred and the bone was removed, when the nervous symptoms previously referred to entirely ceased.

A third specimen was what appeared to be a fibrous tumor, fringed with smaller growths, removed by operation from the outer end of clavicle. The point of interest was the probability of this growth recurring if any of the small attachments had been left behind, thus giving rise to the subsequent suspicion that it was recurrent.

On motion, the growth was referred to the Committee on Microscopy.

STATED MEETING, FEB. 9, 1870.

Dr. Joseph C. Hutchison, President, in the Chair.

SUDDEN DEATH WITH INSIGNIFICANT LESIONS.

Dr. Finnell exhibited two specimens. The first consisted of the heart, kidneys, portion of the aorta and bladder removed from a colored steamboat-hand, thirty-five years of age, who was found dead in his berth. He retired in his usual health, and during the day previous worked with his usual industry and spirits. The autopsy was made twelve hours after death, and revealed an extensive atheromatous condition of the aorta with thickness of its walls, and insufficiency of the aortic and ventral valves. Both kidneys were the seats of extensive degeneration; the right weighed less than one ounce and a half, the left five ounces. The former organ was most extensively congested, blood flowing freely from it on section, and more than one-half of the cortical portion had entirely disappeared. The right kidney was also much disorganized. The bladder was the seat of intense hypertrophy, and would hardly hold two ounces of urine. Its walls were fully half an inch in thickness. The verdict was that death was caused by heart disease, no other reasonable cause for death having been found. There was well-marked cirrhosis of liver. The urethra had not been examined.

Dr. Shrady asked if the brain had been examined.

Dr. F. replied in the negative.

A second specimen was the head, sternum, and portion of the attached ribs taken from an old man who had been murdered in Hudson street. His assailant struck him with a shoemaker's knife, and with the first blow severed the tendons of his forearm, and with a second stabbed him in the neck at the root of the sternum, when the weapon glided over the bony surface downwards, as far as the fourth rib, finally entering the left ventricle. Death was almost instantaneous, the pericardium being filled with blood.

Dr. Krackowizer was of the opinion that the small kidney presented by Dr. Finnell was congenital.

TWO CUNEIFORM BONES.

Dr. Mason exhibited the skeleton foot of a dissecting-room subject, with two internal cuneform bones. He had only been able to find three similar cases on record.

MENINGEAL APOPLEXY THE CAUSE OF DEATH IN THE NEWBORN.

Dr. Lewis Smith exhibited a brain showing meningeal apoplexy. It was removed from an infant twenty-eight hours old. The mother was a primipara, and the face presented. Labor lasted thirty-six hours. The delivery took place without instruments. It was not known whether ergot was administered or not. At first it appeared that the infant was still-born, but after considerable effort respiration was established to a certain extent, and continued in that state until death occurred.

At the autopsy the brain was found to be intensely congested, and over its entire surface, as well as in the ventricles, had been an extravasation of blood. As might have been expected, there was an almost complete atalectasis of the lungs, only the anterior portion of the right lung being inflatable. In this portion there were evidences of commencing emphysema. The point of interest, however, was the condition of the brain.

DR. SMITH remarked that this was the third case in which he had made a post-mortem examination under like circumstances and found the bloody effusion. In one of these three instruments had been used. He believed that very many of the deaths of infants could be explained by this trouble of the brain, when under other circumstances the little one, from the establishment of respiration, might be expected to live.

DR. LOOMIS asked if the emphysema was the result of the inspiratory or expiratory act.

DR. SMITH ascribed it to the former.

DR. LOOMIS stated that in tuberculosis of the lung the opposite was the case, being the result of imperfect emptying of the lung.

LYMPHO-SARCOMATOUS TUMORS.

DR. LOOMIS presented a tumor taken from a German thirty-six years of age, who was admitted into Bellevue Hospital about the twentieth of last December. He was free from any hereditary or acquired constitutional disease, and had always been perfectly healthy until two years and a half ago, when he first noticed a swelling a little behind the right clavicle, composed of a number of smaller tumors. These latter finally united, forming a tumescence of considerable size. About this time similar swellings appeared in the armpits and groins, and subsequently, six months before his admission, he observed another tumor about the centre of the sternum, near the median line. With the development of these growths the strength of the patient failed so rapidly, that as long ago as four months previous to his admission he was unable to walk across the room without assistance. His digestion and appetite were all this time perfect. He had no pain anywhere, neither was there any difficulty in breathing. At the time of his admission he was very much emaciated, was extremely pale and anæmic, and he was so prostrated as to be unable to get in and out of bed unaided. His appetite was still good, rather unnaturally so, desiring more food than he could get. The tumor in the neck was so large as to amount to a deformity, extending as high up as the base of the skull. There was a swelling on the left side of the neck, about one-third the size of the former. The tumor of the sternum was the size of an egg, and was not movable. The axillary masses were only slightly movable, averaged in size a pigeon's egg, and were more or less united. Firm pressure upon the abdomen discovered tumors along the spinal column. There was almost complete aphonia. Physical examination of the chest revealed the thoracic organs healthy. His pulse was feeble, but not much accelerated; no night sweats; no cough. From his entrance into hospital he steadily emaciated. On the twentieth of January he was seized with great difficulty of breathing, necessitating artificial respiration, and from that time until his death he suffered more or less from dyspnœa. He finally died, apparently from exhaustion, on the twenty-second of last month.

Autopsy.—Brain and meninges normal, save a slight sub-arachnoid effusion. The neck on both sides was very much enlarged. On removing the integument the tumor of right side was found to have extended from the base of the brain along the neck to clavicle, and underneath it. The mass was lobulated and multiple, the smaller tumors varying in size from a pea to a hen's egg. The mucous membrane of the larynx, especially the upper portion, was thickened, and presented points of ulceration distributed over the epiglottis and vocal cords. The right pleural cavity was a third filled with serum, in which were floating flocculi of recent lymph. This probably explained the dyspnœa. Scattered throughout the lung substance were little nodules the size of a pin's head. These corresponded in their position to the smaller bronchi, while some appeared to be developed in the walls of the larger tubes, giving rise to dilatation. The bronchial glands were somewhat enlarged.

The stomach and liver were normal. The spleen was much enlarged, and was six inches in its long and four inches in its short diameter. Through its substance were scattered nodules of whitish color, varying in size from a pea to a pigeon's egg. Throughout the intestines were spots of ulceration corresponding to the follicles, and most marked in the large intestine. This accounted for more or less diarrhœa during life. The mesenteric glands were enlarged, and a chain of enlarged lumbar glands extended from the diaphragm to the bifurcation of the abdominal aorta. On the anterior portion of the mediastinum was a tumor opposite the lower border of the sixth rib (four inches by two inches). This corresponded to another growth on the outer portion of sternum already referred to. These had no connection with each other. The several growths examined microscopically were found to correspond with what Virchow has styled lympho-sarcoma.

The blood of the patient was examined during life, but no abnormal increase of the white corpuscles was made out.

DEATH FROM TYPHOID FEVER ON FIFTIETH DAY—HEMORRHAGE, TRANSFUSION, ETC.

DR. JACOBI presented portions of intestine taken from a lady thirty years of age, who had died on the fiftieth day after having been seized with typhoid fever. She was taken some time in December with the usual chill, very soon after which intense diarrhœa set in, which, after continuing for two or three days, was to a certain extent controlled by small doses of alum and tincture of opium. She progressed very well until the ninth day, when she was suddenly seized with hemorrhage from the bowels, which was so severe that it threw her into collapse in one hour. It was only by the application of large quantities of ice (30 pounds) to the abdomen that the flow of blood could be arrested. This was accomplished in the course of half an hour, the patient being in the meantime pulseless and apparently dying. After waiting a time and expecting her to die every minute, transfusion was resorted to, four and a half ounces of defibrinated blood being injected. The change in her condition was exceedingly satisfactory, and the pulse decreased in frequency to one hundred and twenty, and stayed there. After this nothing untoward occurred until the seventh week, when the pulse would range from 140–150, and the temperature would go up to 104½°. The fæcal evacuations appeared tolerably normal and were irregular as to frequency, sometimes two or three in a day, and at other times but one in twenty-four hours. She would complain of pain and uneasiness over her bowels, a symptom which had been more or less constant ever since the commencement of the fifth week. Her appetite and digestion were good. She took large quantities of brandy, beef-tea, and milk, and she seemed as if she ought to get well, but continued notwithstanding to lose ground daily, and finally sank on the fiftieth day.

During the last week or two of the life of the patient, Dr. J. thought of repeating transfusion, but he became satisfied, from the quantities of food taken, the apparent good digestion, and the persistently increasing weakness, that extensive ulceration of the intestines and disease of the lymphatic glands existed, and gave up the idea accordingly.

On making the post-mortem examination, as usual the largest ulcers appeared in the small intestine in the neighborhood of the valve. These lesions were in all stages of development, from the commencing redness and deposit to the final cicatrization, giving evidence in their course of a constant renewal of the diseased action in the gut. A large portion of the colon was in the same condition—the solitary follicles were swollen to an immense size, and the whole surface of the mucous membrane was much congested. These swellings were found, on section, to contain the characteristic grayish-white matter. These intestinal lesions as a whole explained the reason why the pulse would never go down nor the temperature decrease.

The condition of the colon was also of interest in connection with the protracted character of the case. The mesenteric glands were much redder than they should have been, as they were long past the time when they ought to have been congested and enlarged. The spleen had been very large during life, and, although somewhat decreased at death, was still five and a half inches in length.

In answer to a question from Dr. C. C. Lee he stated that for transfusion in this case he used only a plain glass syringe and trocar. The vein was secured, incised, the trocar introduced, and a little blood allowed to ooze through the canule. The syringe was then applied, being cocked upward to prevent the admission of air, and the blood slowly injected. The blood was procured from the husband of the patient, was defibrinated by being whipped as it flowed, filtered through a handkerchief, and afterwards warmed. In consequence of the blood being a little below the normal temperature, the patient suffered after the transfusion from a severe and protracted chill.

(To be continued.)

Medical Items and News.

A MONTHLY Medical Journal, called the *Baltimore Medical Journal*, has been started in Baltimore, Md., E. Lloyd Howard, M.D., and T. S. Latimer, M.D.; are the Editors and Publishers. The January number opens with an interesting paper on the "Pathology and Treatment of Hæmorrhoids," by Prof. N. R. Smith; the remaining pages are devoted to "Selected Articles" of practical interest. As this Journal will not be the organ of any clique, it should have the confidence and support of the profession.

COMPOUND DISLOCATION OF ASTRAGALUS.—Dr. Geo. T. Campbell, of Skaneateles, N. Y., reports an interesting case of compound dislocation of left astragalus. The patient was twenty-five years old, and received the injury by being thrown from a horse.

"There was a ragged wound, extending nearly half around the ankle; a double luxation of the astragalus; the posterior tibial artery torn across, with about two inches of the proximal end hanging from the wound." The surgeon removed the fragments of bone instead of amputating, and the result proved the wisdom of his choice. The case was dressed afterward as an ordinary compound fracture, and one year after the accident the patient walks with very little perceptible limp.

DEATH OF A NOTED LITHOTOMIST.—Prof. Benjamin Winslow Dudley, widely known in the West and the South as a lithotomist, and as a successful teacher of surgery, died in Lexington, Ky., on Thursday, January 20th, 1870, aged 80 years.

DEATHS FROM PULMONARY TUBERCULOSIS.—Ninety persons died of consumption in Lynn, Mass., in 1869.

THE ARMY MEDICAL MUSEUM IN WASHINGTON, D. C.—Twenty-five thousand three hundred and seventy-three visitors registered their names at this Museum during the year 1869. There are 12,220 catalogued specimens, an increase of 2,176 specimens during the year.

THE MEDICAL BOARD OF THE EASTERN DISPENSARY has been reorganized, and the following officers have been elected: Dr. R. J. O'Sullivan, President; Dr. Verranus Morse, Vice-President; and Jonas P. Loines, House Physician of the Dispensary, Secretary. The meetings are to be held on the second day of every month at 11 A.M. Several interesting papers have been promised.

THE PRODUCTION OF SALT IN NEW YORK STATE.—In 1869, the Onondaga salines produced 6,804,295 bushels of boiled salt, and 1,857,942 bushels of sun-made salt—a total of 8,662,237 bushels, of 56 pounds each. The total revenues were $86,757.60. The net revenue to the State was $41,211.03. There have been manufactured at the Onondaga salt springs, since 1797, 200,781,490 bushels of salt. Since 1846, when the duty was reduced to one cent a bushel, the State treasury has received from the salt springs a net revenue of $517,587.43.

THE FIRST HUMAN DISSECTOR.—The first to make human dissections was Vesalius, of Spain. He was sentenced to the Holy Land, and died at sea on his return homeward.

THE MEDICAL MUSEUM OF WILLIAM HUNTER.—This distinguished surgeon, who was the teacher of Matthew Baillie in morbid anatomy, and of his brother, John Hunter, in surgery, left a museum of his own collecting, which at his death was valued at £20,000.

The greater part of it is now in the possession of the University of Glasgow, to which he bequeathed it. —*Boston Med. & Surg. Journal.*

HUMAN ANATOMY A SCIENCE.—To the illustrious Velpeau we owe the first attempts at making human anatomy a science.

DISTINGUISHED ENGLISH AND AMERICAN SURGEONS.—Cooper and Cline of London were graceful and accomplished operators; while Abernethy and Hunter, less showy in their operations, excelled in their pathology and knowledge of disease. Abernethy showed the great importance of the principles of surgery, while Cooper and Cline showed how much elegance there was in a nice operation.

There was the same difference between Mott and Stevens of New York. The former excelled in the nicety of his operations, while the latter was superior in pathology and practical knowledge. It was a common remark thirty years ago, that a patient should consult Stevens in regard to the propriety of an operation, and if he advised it, have Dr. Mott perform it.

WASTE OF NIGHT SOIL.—Mr. Waring (*Jour. of Applied Chemistry*) estimates the direct annual loss to the country by the waste of night soil at $50,000,000. The indirect loss in the falling off of the producing power of the land is left out of view, and the other, far more serious, loss of life occasioned by diseases brought on by open privies, cannot be computed in money, accord-

ing to Prof. Charles A. Joy, but must especially attract the attention of every student of social science in the country.

Collodion for Surgical Purposes.—Collodion was first used in surgical cases by J. P. Maynard, a medical student of Boston, in 1847.

The Discovery of Aniline.—This dye is not a very recent discovery, as many imagine. It was first found in 1826, among the products of the dry distillation of indigo. It was originally called *crystalline*. When first obtained from coal tar, in 1837, it was called *kinlo.—Jour. Applied Chemistry.*

A Case of Rupture of the Uterus—Recovery.—Dr. Strong (*Buffalo Med. and Surg. Journal*) recently reported a case of rupture of the uterus to the members of the *Buffalo Medical Association*, resulting in recovery, which occurred under his observation in Washington, D. C. The patient, a primipara, did not have a very severe labor; but before the head reached the superior strait, the pain suddenly ceased, the head receded, and, upon examination, it was found that the child had escaped through a rent in the uterus into the peritoneal sac. The feet were seized and the body delivered, but it was necessary to apply the forceps free to the head. The patient recovered, and a careful examination made five or six weeks afterward revealed no trace of the injury.

The case was reported on account of the extreme rarity of recovery after so grave an accident. The records of about 44,000 cases of labor show sixty-five cases of rupture of the uterus, and only six or seven recoveries.

On the Use of Veratrum Viride.—George A. Ward, M.D., New Haven, Ct. (*The Jour. Med. Medica*), now confines himself to the use of a saturated tincture of the root, which is found uniformly reliable. The subjoined formula is a favorite one with him:

℞ Sat. tr. verat. viride... ʒj;
Potassæ chlorat..... ʒij;
Aquæ ..... ℥ij. M.

If to a child, he adds a little syrup. The chlorate of soda is sometimes substituted for potassa, as the taste is more agreeable. Dose: One teaspoonful every two hours for three doses; once in three hours for two doses; once in four hours for two or three doses, according to the effect produced. Given in this way, no deleterious effects or emesis will be produced.

An Instrument-Handle from a Thigh-Bone.—A materialistic surgeon of Paris recently exhibited to one of his friends an instrument, the handle of which was carved in bone. "Do you know," he asked, "of what this handle is made?" "Of ivory, I suppose." "No," said the doctor, while tears almost choked his voice, "it is the thigh-bone of my poor aunt."—*Med. and Surg. Reporter.*

English Customs in the Time of William the Conqueror.—The hours kept by our ancestors of Great Britain were primitive enough, as is attested by the following Norman proverb:—

"To rise at five, to dine at nine,
To sup at five, to bed at nine,
Makes a man live to ninety-nine."

Codeine.—This alkaloid, from *kode*, poppy-head, was discovered in opium by Robiquet, in 1833. Its composition answers to the formula C^{36} H^{24} NO^{6}.

Retention of Fœtus in the Uterus for Eighteen Months.—M. S. McMahon, M.D., of Suisun City (*Pacific Med. and Surg. Journal*), asserts that in a recent case of pregnancy the fœtus remained in utero for nearly a year and a half. The placenta contained a fœtus 4½ inches in length, having an appearance of old sponge or mummy.

Removal of a Horse-Shoe Pessary from the Female Bladder.—Prof. W. H. Byford, of Chicago (*Chicago Med. Examiner*), was called to a young married lady, who was suffering severely from pain in the region of the bladder, which was produced by the presence of a horse-shoe pessary, inserted by the family physician into the bladder by mistake, instead of the vagina. The patient was placed under the influence of chloroform, and the time occupied by the efforts at extraction was about ten minutes. It measured 1¼ inches from one side to the other, and was 2½ inches long. The diameter of the rod was three-eighths of an inch. The extracted instrument was incrusted with the urinary deposits nearly all over. It had been in the bladder about three months.

The Origin of Syphilis in Europe.—M. Auzias-Turenne has lately addressed the Academy of Medicine in favor of the Transatlantic origin of syphilis. The talented syphilographer bases his views on three orders of proofs:—1st (historical), the writings of Oviedo, Thevet, Roderic Dias, showing the importation of syphilis, and its progress through Spain, Italy, and France. 2d (horological), to wit, the generalization and the benignity of the disease when first observed in the West Indies, its progress through Europe, insidious at first, then speedy and terrible, and now generally waning away; 3d (philological), to wit, all the appellations of the disease and its symptoms, which have been found in the Caribbean dictionary, and in the vocabulary of the Indians, with the exception of the names of those diseases which we have exported to America. Having thus advocated this theory of the importation of syphilis from the Far West, M. Auzias-Turenne winds up with the following practical conclusion: Syphilis has come from America; we must renounce as a general method its traditional treatment by mercury; the ill must become its own remedy and its own preservative.—*Lancet.*

The Fate of Medical Students.—In a brief and brilliant article that forms a part of the fifth volume of the St. Bartholomew's Hospital Reports, Mr. Paget has, with much labor and considerable perspicuity, given the reader an analysis of the careers of 1,000 medical students, all of whom have been known to and observed by him or by his colleagues, Mr. Callender and Mr. Thomas Smith, during a period of fifteen years. He has placed them in eight divisions, and tells us that 23 have achieved distinguished success, 66 considerable success, 507 fair success, and 124 very limited success; that 56 failed entirely, 96 left the profession, 87 died within twelve years of commencing practice, and 41 died during pupilage.

Medical Schools in Italy.—The chief Italian medical schools are situated at Bologna, Florence, Pisa, and Turin. The University of Bologna ranks among the most ancient in the world. Founded as early as 1119, it rapidly gathered students from all parts of the globe to the number, in 1216, of ten thousand. It was at Bologna that anatomy was first taught, in the fourteenth century; and it was there, towards the close of the fifteenth, that Joseph Galvani made the discovery which has transmitted his name to all time. At present the number of students in all departments is only about four hundred.

Florence possesses the finest collection of anatomical models in wax in the world.

Pisa, though sadly degenerated, still has the finest school in Tuscany.—*Correspondent Cinn. Lancet and Observer.*

Prostitution and Venereal Diseases in Paris.—The following statistics on prostitution and venereal diseases are extracted from a work on "Prostitution in Paris, and account of propagation of venereal diseases among women," by Dr. Leon Le Fort, surgeon of Cochin Hospital.

In 17 months he treated 1,824 cases in the hospital, and 12,889 outside. The patients he divides in the subjoined classes: 1st. Wives and concubines. 2d. Unpaid mistresses. 3d. Women met at the public balls. 4th. Women met on the street. 5th. Inmates of houses of prostitution.

Dr. Le Fort gives the particulars of 4,987 cases. The *first class* is put down for 3 cases of soft chancre, 9 cases of the Hunterian variety, and 63 cases of blennorrhagia.

On inquiring whether their calling or occupation had any influence, it was found that distance from home was a cause, and that bakers figured the highest on the list; these working-women only go about at night, and are almost always at a distance from their residences.

The *second class* is put down for 576 cases of urethritis, 82 of soft chancre, 171 hard chancre—a total of 829 cases. In 616 cases, the occupation of the women was known: Domestics figured oftenest (109); seamstresses (79); washerwomen (64); 44 cases were married women, of which twenty-five had urethritis, five soft chancre, and fourteen hard.

Women met at public balls should be regarded as clandestine prostitutes; 541 cases are classed according to location and where the diseases were contracted.

1,761 cases are noted occurring among women found on the public streets. 780 cases in houses of prostitution are recorded, and those which furnish the greatest number are situated near the military school, Hotel de Ville, Palais Royal.

These statistics show that clandestine prostitution is most dangerous.

From January 1st, 1861, to the 31st of December, 1866, a period of six years, of 13,818 women arrested for clandestine prostitution there were 3,725 cases of disease.

Of 2,303 unregistered women arrested annually, one out of three was found infected; while at the same time out of 3.850 registered women, only one out of seven was diseased.

The number of clandestine prostitutes in Paris is estimated at 20,000. Of the 13,818 arrested, 1,549 only wished to be registered. During the past six years 7,277 have been reclaimed by their families.

Cutaneous Horn.—Mr. Houghton, of Dudley, in Worcestershire, recently presented to the dermatological section of the museum of the Royal College of Surgeons, a remarkable specimen of cutaneous horn, which grew from the skin of the under surface of the last phalanx of the great toe. It had been two years in formation, the patient being a woman aged 66. It measures one inch in length; its breadth is seven lines, or rather more than half an inch; and thickness, a quarter of an inch.—*Jour. of Cutaneous Medicine.*

Aniline Dermatitis.—Cases of *aniline dermatitis* are often met with in England, by Dr. Erasmus Wilson and other dermatologists, caused by wearing purple or red socks or stockings, dyed with the aniline pigments. It seems to be a very remarkable and troublesome affection. As soon as recovery appears to be complete it breaks out again.

Dr. Wilson believes that the nerves themselves are poisoned by the dye, and that the morbid phenomena produced by the poison are repeated periodically.—*Jour. of Cutaneous Medicine.*

Infant Mortality.—In London, in every one thousand deaths, 160 occur among infants under one year of age. One-fourth to one-half of the whole mortality in New York city is to be found among children under one year of age. In San Francisco, out of every thousand deaths, 300 infants of one year of age, or thereabouts are recorded.

The Society of the Alumni of the Medical Department of the University of the City of New York met in the College, East 26th street, on Tuesday evening, Feb. 22d, Dr. S. S. Purple, the President, in the Chair, assisted by Drs. H. S. Hewit and F. D. Lente, Vice-Presidents. The reports of the Secretary, Dr. H. M. Brush, and of the Treasurer, Dr. C. I. Pardee, were read. The following officers were elected for the ensuing year:—*For President*, Samuel S. Purple, M.D. *For Vice-Presidents*, James B. McGaw, M.D.; Daniel Ayers, M.D.; Solomon S. Satchwell, M.D.; Henry S. Hewit, M.D.; Frederick D. Lente, M.D.; James R. Leaming, M.D. *For Secretary*, Charles I. Pardee, M.D. *For Treasurer*, William B. Lewis, M.D. *For Orator*, F. D. Lente, M.D.; *Alternate*, D. B. St. John Roosa, M.D. *For Committee on Nominations and Arrangements*, D. B. St. John Roosa, M.D.; F. V. White, M.D.; A. W. Stein, M.D.; J. H. Anderson, M.D.; S. I. Clark, M.D. The Society then adjourned to the Lecture Room, where, after prayer by Rev. Isaac Ferris, D.D., LL.D., Chancellor of the University, Dr. James R. Leaming delivered an interesting address on the Progress of Medicine. The address was ordered to be printed, on motion of Professor Post.

Horseflesh.—The Society for the Propagation of Horseflesh as an Article of Food says that the consumption of this aliment is increasing throughout Europe. In three months there were sold in Paris 273,000 pounds of it. There is also a great consumption of it in the provinces.

Increase of Carbuncle in Scotland.—The Registrar-General of Scotland states that deaths from carbuncle are on the increase, and that the mortality from it has been getting larger and larger ever since the lung disease of cattle was imported into Scotland.

ON RELAPSING FEVER.

By A. CLARK, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE I., PART II., FEB. 7, 1870.

As the study of cases is the only possible means of ascertaining the real characters of disease, I urge you to examine carefully those that are still to be recited.

CASE II.—DISTINCT CHILLS WITH ATTACK AND RELAPSE, LASTING TEN AND FIFTEEN MINUTES; SEVERE MUSCULAR PAINS; FIRST STAGE, FOUR DAYS; SECOND STAGE, TEN DAYS AND A HALF; RELAPSE ON FOURTEENTH DAY; THIRD STAGE, FOUR DAYS.

Hiram S., æt. 24, single, merchant, South Carolina, entered December 28, 1869. During the night of 25th December was taken with a chill, lasting ten minutes, followed by fever, severe headache, and thirst; no remission up to time of entering hospital. On admission temp. 102½°; pulse 120; skin hot and dry; tongue dry and coated. Ordered liq. ammon. acetat.

Dec. 29th. High fever; pain in right iliac fossa.

Dec. 30th. Last night had a profuse sweat, and this morning every symptom of fever has disappeared. Pulse is 80; temp. 97½°. Complains of pain in the head, back, and calves of legs.

Patient has a gonorrhœa, and now treatment commenced for it. Pulse and temperature normal from Jan. 1st to Jan. 8th.

Jan. 9th. Early this morning patient had a chill, lasting fifteen minutes, followed by fever, headache, etc.

Jan. 11th. Pulse 130; temp. 102½°. Commenced vomiting. Great pain in back and head.

Jan. 12th. Still high fever. Temp. 104°; pulse 132.

Jan. 13th. Skin moist. Temp. seems normal to hand. Patient does not move a limb, owing to severe muscular pains.

Discharged Jan. 24th, still debilitated. Pulse and temp. normal during last week.

CASE III.—TEMPERATURE 108½°* ON THIRD DAY OF RELAPSE; FIRST STAGE, SIX DAYS; SECOND STAGE, EIGHT DAYS; RELAPSE ON FOURTEENTH DAY; THIRD STAGE, FOUR DAYS.

James C., æt. 15, single, New York, admitted December 26, 1869. Patient has been much exposed to the weather for four weeks, and has been sleeping on a damp floor during this time. States that he fell sick four days ago, with headache, pains in his limbs, loss of appetite, and fever. On admission face is flushed, eyes suffused, tongue furred. Pulse 132, and temp. 105°. Bowels have not moved since he became sick. No cardiac or pulmonary disorder. Ordered a cathartic and one drop tr. aconiti rad. hourly. Evening, pulse 132; temp. 105°.

Dec. 27th. Pulse 132; temp. 104°. Same in evening.

Dec. 28th. Defervescence, with sweating. Pulse 100; temp. 96°. Evening, pulse 92; temp. 96°.

Dec. 29th. Pulse 88; temp. 99°. Evening, pulse 88; temp. 98°.

Dec. 30th. Eats well, and wishes to get up.

Jan. 4th. Relapse. Chilly feelings; severe headache, etc.; went to bed again; bowels open.

Jan. 6th, P.M. Pulse 136; temp. 108½°. Face flushed; urine 1016; alkaline. No albumen.

Jan. 7th. Pulse 148; temp. 104½°. Skin dry; pain in legs and feet; gurgling and tenderness in right iliac fossa; no eruption. Evening, pulse 144; temp. 105½°. Tr. aconit. rad., gtts. iij., repeated in two hours.

Jan. 8th. Pulse 96; temp. 96°. Sweating profusely. Evening, temp. 98°.

Jan. 9th. Pulse 84; temp. 99°. Feels well.

Jan. 19th. Pulse and temp. normal since last report.

You may learn the habits of the disease somewhat more fully from the following abridged or outline reports:—

CASE IV.—Margaret ——, widow, aged 24, born in England, occupation housekeeper, attacked November 3d.

Nov. 4th. Vomiting; nose-bleed, and high fever.

Nov. 6th. Admitted into hospital.

Nov. 6th, 7th, and *8th.* Fever continued; temperature steady, at 104°.

Nov. 9th (Sixth day). Sweating profusely. Temp. 97½°.

The remission lasted seven days. On the evening of Nov. 15th, the temperature was still 97½°.

Nov. 16th (Thirteenth day). Headache and chilly feelings, and the temperature rapidly rose to 104; on the 17th it reached 106½°.

Nov. 18th. Evening. Feels well, but temp. 105½°.

Nov. 19th. The usual sweat, and temp. normal. This is the beginning of convalescence.

Thus we have the first attack lasting six days, the remission seven days, and the relapse three. The highest temperature was 106½°, and here we notice among the symptoms bleeding from the nose.

CASE V.—Mary R., æt. 18, single, domestic, admitted Nov. 15th, attacked Nov. 10th with the chill and fever. On the first day there was *diarrhœa.* On the 16th (sixth day) there was epistaxis and tenderness in the right iliac fossa, and on that day the highest temperature (105°), and on the 18th epistaxis again, although the usual crisis had occurred in the night preceding.

Nov. 25th (Fifteenth day). Relapse, and temp. 107°.

Nov. 27th. Epistaxis again; temp. still 107°; and pain in the back, legs, and shoulders.

Nov. 30th. Sweating and rapid subsidence of fever. Duration: the first fever between seven and eight days; of the intermission, a little over seven days; and of the relapse, five days. There is recurring epistaxis, diarrhœa at the onset, and on the sixth day tenderness in iliac fossa. Highest temperature 107°. The patient stated that other members of the family with whom she lived were sick with the same disease. She came from a crowded tenement house.

CASE VI.—Mary W., æt. 35, widow, born in England, was attacked Nov. 20th, and admitted on the same day. The fever subsided after three days. At that time the menses, which had been suppressed for six months, appeared; and an eruption was noticed on the abdomen—purple spots, which disappeared on pressure. The relapse occurred (Nov. 31st) on the

* Niemeyer (Prac., vol. ii., p. 570, Am. ed.) quotes from Wünderlich, who made the thermometer an instrument of prognosis, the following statements relating to typhus and typhoid fevers:—"In typhus, all the patients in whom the temperature reached 105° died; and of fourteen that died, five, or more than one-third, had this high temperature. Of the patients whose temperature never rose above 105·5°, not one died." Referring to typhoid fever, he says (p. 589):—"We may look for the approach of death if the temperature remain for some time at 107°; if it suddenly rise to 107 5°, or 108°; or if it suddenly fall very low, say to 94°." This case shows that in relapsing fever the temperature may rise to 108½°; and another in this series, that it may stand for two or three days at 107° in persons who are to recover, and who do recover as rapidly and perfectly as those in whom it at no time, either in the first or third stage, exceeded 102½°.

In this series we have no instance in which the temperature fell as low as 94°; but there is one in which, after defervescence, it stood for one or two days at 95½°, without any unfavorable influence.

twelfth day, and the second critical sweat (Dec. 3d) at the end of four days. The highest temperature (105°) was reached the day before the second crisis.

CASE VII.—Mary S., æt. 32, single, born in Germany, domestic in a poor family, attacked Nov. 24th, admitted Dec. 1st. Temperature on admission 105°. On the eighth day of the fever the menses appeared. Fever subsided on the ninth day with sweat. Remission lasted eight days; relapse on the eighteenth day (Dec. 12th), then five days of fever, terminating in a sweat Dec. 17th. There is probably a mistake of two or three days in the date of the attack in this case. The patient was not intelligent. The highest temperature was reached on the third day of the relapse, 106°.

CASE VIII.—Henry G., æt. 17, born in this country, attacked Dec. 13th, admitted Dec. 17th. The usual symptoms, including chill and pain in the limbs; sweat and defervescence after five days (Dec. 18th); relapse on the fifteenth day (Dec. 28th) after *ten days* of remission; on the second day of the relapse epistaxis and diarrhœa; two days later the highest temperature, 102°, in the evening; the next morning fever had subsided, diarrhœa had ceased, patient sweating freely, temperature 98°.

CASE IX.—Mary W., æt. 35, single, domestic, attacked Dec. 14th, admitted Dec. 20th. This fever was attended with intense headache. The temperature was 105½° on the day of admission. The next morning it had fallen to 97° during a profuse sweat. Now there were *sudamina*, and there was tenderness in the right iliac fossa; remission lasted eight days and relapse occurred on the fifteenth day (Dec. 29th); the second fever lasted seven days, subsiding with the usual crisis Dec. 5th. Highest temperature 106°, on the first day of the relapse.

CASE X.—BILIOUS VOMITING; JAUNDICE IN RELAPSE; FIRST FEVER, FIVE DAYS; INTERMISSION, FIVE DAYS; RELAPSE ON ELEVENTH DAY, LASTING THREE DAYS; HIGHEST TEMPERATURE 103½° ON FIRST DAY OF RELAPSE.

Mary F., æt. 30, born in Ireland, domestic, entered Dec. 27th. Attacked on 25th with chilly sensations, pain in the back and lower extremities, and headache. At night there was high fever and bilious vomiting.

On December 27th, 28th, and 29th, the temperature was 103°. Vomited occasionally.

Dec. 30th. Temp. 97°; appetite returns, and skin covered with perspiration.

Jan. 4th. Well and up to-day, when she had a chill; headache; tongue now dry and brown, and temp. 103½°.

Jan 6th. Has become jaundiced.

Jan. 7th. Morning, temp. 103. Night, temp. 98°. Sweating. Is still slightly jaundiced.

Jan. 15th. Pulse and temperature normal all last week.

CASE XI.—ABORTION; FIRST FEVER, THREE DAYS; INTERMISSION, EIGHT DAYS; RELAPSE ON ELEVENTH DAY, LASTING THREE DAYS AND A HALF; HIGHEST TEMPERATURE, 105°, ON THIRD DAY OF RELAPSE.

Mary F., æt. 15, single, domestic, entered in November to await confinement. Dec. 29th, seized with chills, muscular pains, nausea, vomiting and debility. High fever on the 29th and 30th, and on Dec. 31st she miscarried. On Jan. 1st, temp. 104°, but commenced sweating, and in the evening the fever disappeared.

Jan. 9th. Another chill; vomiting; high fever.

Jan. 11th. Pulse was 130, and temp. 105°.

Jan. 12th. Evening, sweating again.

Jan. 13th. Temp. 97½°; debility; muscular rheumatism.

CASE XII.—FIRST STAGE, FOUR DAYS; SECOND STAGE, NINE DAYS; RELAPSE ON FIFTEENTH DAY; THIRD STAGE, THREE DAYS; HIGHEST TEMPERATURE, 106°, ON THIRD DAY OF RELAPSE.

Emily R., æt. 27, married, born in England, domestic, admitted Dec. 29th. Attacked on 26th. Pain in limbs; chill of one hour's duration, followed by fever and headache.

Dec. 31st. Highest temp. in first attack 104½°.

Jan. 1st. Perspiring; temp. 97°.

Jan. 10th. Relapse, chill, followed by fever.

Jan. 12th. Evening, highest temp. 106°.

Jan. 13th. Profuse sweat, which commenced yesterday evening. Temp. 97½°. Has rheumatic pains all over body.

Patient states others in the same house were sick in the same manner she was.

CASE XIII.—DIARRHŒA; SEVERE PAINS; FIRST STAGE, FOUR DAYS AND A HALF; SECOND STAGE, NINE AND A HALF DAYS; RELAPSE ON THE FIFTEENTH DAY; THIRD STAGE, FOUR DAYS; HIGHEST TEMPERATURE ON THIRD DAY OF RELAPSE, 106°.

Rosanna P., æt. 35, born in Ireland, widow, admitted Dec. 31st.

Dec. 28th. Chills and fever with sweating. On admission, abdominal pain, hot skin, intense headache, diarrhœa, and pain in calves of legs. Critical sweat on night of Jan. 2d. Relapse Jan. 12th, chills, aches, and pains, muscular, articular, and cephalic; nausea and vomiting; temp. 104½°.

Jan. 15th. Diarrhœa; highest temp. 105°; sweating.

Jan. 16th. Temp. 96°, but pains continue.

CASE XIV.—FALSE CRISIS ON THIRD DAY; FIRST STAGE (INTERRUPTION INCLUDED), FIVE DAYS; PULSE FELL AFTER TRUE CRISIS TO 54, TEMPERATURE TO 95½°; HIGHEST TEMPERATURE 105°, ON THIRD DAY; DISEASE TAKEN IN THE HOSPITAL, PROBABLY; NO RELAPSE AFTER FIFTH DAY.

Ann C., æt. 37, Ireland, domestic, admitted Jan. 3d. Patient complained only of weakness and dull pains in calves of legs on admission. Temperature and pulse were normal, and she was supposed to be a malingerer.

Jan. 12th. Had a sharp chill, followed by high fever and vomiting of bilious matter. Pulse 120; temperature 103°.

Jan. 14th. Pulse 112; temperature 104½°; sweating.

Jan. 15th. Pulse 86; temperature 97°. In evening, fever again; pulse 108; temperature 105°; vomiting a great deal; headache; rheumatic pains.

Jan. 17th. Profuse perspiration; pulse 90; temperature 95½°.

Jan. 18th. Pulse 80; temperature 95½°.

Jan. 19th. Pulse 54; temperature 97°.

Jan. 24th. Pulse and temperature have been normal since last entry. Bowels now regular. Yesterday sat up all day; still complains of pain in left shoulder.

No eruption, epistaxis, or jaundice in this case.

Jan. 29th. Up to date pulse and temperature normal. Still has pains in left arm and shoulder; appearance of limb normal; patient improved rapidly, and was discharged Feb. 17th.

It will be seen that in this case there was no relapse on or near the fourteenth day; that on the evening of the third day there was sweating, and the next morning an intermission, pulse at 86, and temperature 97°, lasting less than a day, and that the fever finally subsided with another sweat at the end of five days. The case was kept under observation for a month after the fever ceased. I have seen no notice of such behavior in the European cases.

CASE XV. — CRITICAL SWEAT VERY COPIOUS; FIRST STAGE, FIVE DAYS; INTERMISSION, FOUR DAYS; RELAPSE ON THE TENTH DAY, IF PATIENT'S STATEMENT IS TRUE; THIRD STAGE, FIVE DAYS AND A HALF; HIGHEST TEMPERATURE, 105½°, ON FIFTH DAY OF RELAPSE.

Thos. King, æt. 27, single, Ireland, laborer, admitted Jan. 8th.

Dec. 3d. Chilly feelings followed by burning fever, dry cough, thirst, and headache. These symptoms continued for five days, when he had such a perspiration as to wet bed-clothing through. After this felt well until two days before admission, when he had another chill followed by the usual symptoms of the relapse.

Jan. 11th. Reached highest temperature, 105½°.

Jan. 12th. Temperature 98°. Had sweat last night; fever gone.

In the preceding cases the relapse has fallen on the day Dr. Aitkin has appointed for it but twice. Here is one that falls under his rule exactly.

CASE XVI.—FIRST STAGE, SEVEN DAYS; SECOND STAGE, SIX DAYS; RELAPSE ON THE FOURTEENTH DAY, LASTING THREE DAYS.

Chas. Smith, æt. 37, native, boatman, admitted Jan. 13th, 1870. Patient states that on Dec. 30th he was attacked with chilly sensations, nausea, slight vomiting, headache, pains in the legs; fever followed, lasting about one week, when he had a profuse sweat, and the fever, nausea, and all signs of disease disappeared, except the muscular pains.

Yesterday, Jan. 12th, had chills and nausea again, and fever reappeared.

Jan. 13th. Pulse 136; temperature 104°.

Jan. 14th. Pulse 136; temperature 104°, both morning and evening.

Jan 15th. Perspiring freely. Pulse 100; temperature 96°. Evening, pulse 60; temperature 97½°. Skin natural. Muscular pains still continue.

I have made some little tables exhibiting some of the facts of the disease that may not be entirely uninteresting. For example, I have one here showing the temperature in a dozen cases:—

HIGHEST TEMPERATURE IN TWELVE CASES OF RELAPSING FEVER.

FIRST FEVER		RELAPSE			
Temperature.	Day of the Disease.	Temperature.	Day of the Relapse.	Temperature at Defervescence.	
104°	3d, 4th, & 5th	106½°	2d	95½	for 2 days; 3d day 97.
103	4th	103½	3d	97½	
104½	5th	106	3d	97½	
104	7th	105½	5th	97½	
105½	7th	106	1st	97½	
105	8th	106	4th	98	
104½	?	105	3d	98	
105	6th	107	1st & 3d	97	
103	2d, 3d, & 4th	103½	1st	97	
104	3d	105	3d	97½	
103	4th	103½	1st	97	
105	5th, morning & evening	108½	3d	96	

You observe the period of highest temperature is not the same in all the cases. Notice also the temperature in the relapse. Here is a fact which has not been observed abroad—that the temperature rises higher in the relapse than in the primary attack. Here is another fact which has not been noted by our European brethren,—the temperature in almost all instances falls below the natural standard in the defervescence. In one case it fell to 95½°, and remained there two days. In all, except the 10th case of the table, it fell below the standard of health.

The length of the several stages of the disease can be seen at a glance in the following table:—

	Duration of first Period.	Duration of Intermission.	Duration of Relapse.
Margaret C.	7	7	3½
Mary R.	7½	7	5
Mary W.	3	7	4
Catherine, night nurse.	4 or 5	8	?
Mary S., according to patient.	10	8	5
Mary W.	8	8	7
Rose M.	5	8	6
Rika B.	6	4 ?	4
Hiram S	6	7	4
Emily R.	6	9	5
Rosanna P.	5	9	4 or 5
Thomas K.	5	4	6

In regard to the mortality of the disease here: Up to the night of Saturday before last there had been received into the hospital 52 cases. Up to Thursday night of last week the Sanitary Superintendent had discovered 92 cases in all the city. When I gave a short account of the disease to the Academy of Medicine last Thursday evening, I expected to say that no death had occurred; but while at the meeting I received a note from Dr. Sproat saying one patient had died in the hospital. Up to that time, then, we had had but one death. In this respect the disease corresponds with the European affection, with which I stated it was identical.

It will be remarked that the chill as an initiatory symptom was not present, or rather was not recorded in two cases, and in several it was no more than a chilly sensation; in one it occurred in alternation with heat, and in another with sweats; repeatedly it was a "sharp chill," and in one it lasted an hour. It was a part of every relapse.

Vomiting of bilious matter occurred in seven; diarrhœa is noted in two; purple spots which disappeared on pressure in one (the same kind of eruption was noticed in another case not included in this series); nose-bleed in three; jaundice in relapse only in two; sudamina in one; abortion in one, the only pregnant woman who had had the disease up to Jan. 24; menstruation or sanguineous discharge from the vagina, both in the attack and the relapse, in one; and restoration of menses in another, after six months' suppression (perhaps not in this series).

Relapse did not occur in the case of one of the two physicians who took the fever in the hospital, yet his fever had the duration, the crisis, and all the distinctive characters of the first stage of relapsing fever. The same can be said of Case XIV., unless the singular intermission, commencing with sweat and ending in recurrence of fever, without chill, after sixteen hours, is to be regarded as separating the first and third stages.

Pain and tenderness in the regions of the spleen and liver are not common symptoms in this epidemic. In no instance did the patient call the physician's at-

tention to either of these organs up to the middle of January. At that time the recording clerk was requested to note the condition of these regions, and three patients were examined by way of illustrating the instructions. In each of these there was a little starting on the percussion of the hepatic region, but the liver was not enlarged perceptibly in either, and there was nothing that deserved the name of pain: but in each there was an easily recognized and nearly painless enlargement of the spleen. It is probable that in this epidemic the spleen is enlarged as frequently as in that noticed by Jenner.

In almost all fevers there is a daily remission. In miasmatic fevers, except the congestive, it occurs in the afternoon or night; in typhus and typhoid we usually notice it in the morning. But in this affection, thus far, the fever is strictly continuous till the crisis occurs, giving, generally, the same rapidity of pulse and the same temperature of the body evening and morning; or when there are variations they arise from the even progress or rapid decline of the disease, and are not repeated the next day.

To show the contagious element of this disease, our hospital contributes a few facts. Out of the nine young physicians who have been brought into close intercourse with the sick, two have taken it; among nine nurses and orderlies in the medical wards, one; of their "helpers," none; among the patients admitted on account of other diseases and treated in the same wards with the relapsing fever cases, numbering probably about two hundred, six have been attacked. In a few instances in the city, whole families have been attacked by it. In one instance seven persons, making the whole of one family, including father and mother, were received at Bellevue. Such occurrences, however, admit of a double explanation, so that the spread of the disease in the hospital furnishes the more positive evidence of communicability. But Dr. Harris finds the contagion active only within a certain limited sphere. Persons in the rooms on one side of a tenement house do not give the disease to those on the other side. Those in the cellars do not spread it to the upper stories. His idea is that the sphere of infection is small, but that within that sphere it is active.

Relative to the period of incubation, one single fact is all we have so far that bears upon it. A woman was received at the hospital whose brother came home sick with the fever and slept one night in the house, and nine days after this sister and a little child were attacked. He slept, however, with four children, and neither one of them took it, while a child who was not in the bed with him did take it. Dr. Harris, in a note to me, says he has found a case in which he can trace the period of incubation, and it appears to have been eleven days. In still another it appears to have been fifteen days. It may not be constant, but it is not likely to be below nine days, and that is about the period of incubation of typhus; and though this disease has only alliances with that, we should not be surprised to find the period of incubation the same.

In regard to the age of those attacked:—

In Europe it is said the disease attacks persons of all ages, from infancy to seventy. Among our hospital patients the oldest has been fifty-six. Some infants and children have been received, but the disease has fallen most heavily on persons between twenty and forty years of age.

The fever seems to attack males and females in about equal numbers.*

Little can be said as yet of the *post-mortem* appearances in this epidemic. In the one fatal case they were looked for, and Dr. Sproat reports in his note that the "liver was enlarged, and the spleen very much so. It weighed two pounds and three ounces, and contained numerous small apophyses. No other lesion was found." So far, then, we have reason to suppose that its pathological anatomy does not differ materially from that of the same disease in Europe.

TREATMENT.

Dr. Rutty, referring to the fever of 1739 in Dublin, writes:—"I was assured of seventy of the poorer sort, abandoned to the use of whey, and God's good providence, who all recovered."

Cormack seems to think that antiperiodics have some influence in preventing the relapse. Robertson and Paterson could not prevent it with quinine, biberine, digitalis, or arsenic. Douglas gave quinine in 24 cases, still the relapse occurred in 22. Smith depended on emetics, diaphoretics, &c., in 200 cases, and concludes that the disease cannot be cut short by any means.

There seems to be a very general conviction among the European physicians that the disease will run its course, do what they may, and therefore that its symptoms afford the only suggestions for treatment. A laxative is recommended in the beginning. Aitkin says, "Five grains of calomel and one grain of opium have been found more efficient in subduing the severity of this symptom (vomiting) than counter-irritation and effervescing draughts. The headache has sometimes appeared to justify the application of leeches to the temples, or a blister to the back of the neck; when the temperature is high, tepid or cold sponging brings some relief."

Dr. Murchison hopes to prevent "the uræmic intoxication, which is one of the main causes of death in uncomplicated cases," by diuretics. He uses two drachms of nitre dissolved in two pints of barley-water daily, the solution acidulated with one drachm of dilute nitric acid; or he would give acetate of potash or nitric ether for the same purpose.

Regarding the treatment of "the post-febrile ophthalmitis," all appear to follow Dr. McKenzie's plan of taking blood locally,—a little will often be enough,—giving calomel and opium to slight ptyalism, and using belladonna and counter-irritation, "as in syphilitis and rheumatic iritis." Dr. Dubois of this city finds that depletion will not do for all cases, and advises quinine and other tonics for those whose general condition is "below par."

In most of our cases no active treatment has been attempted. The disease has a definite course to run, and therefore in its therapeutical relations falls into the same class as measles and scarlet fever. European experience has shown that it cannot be subdued by drugs, or its fever stages shortened. Nothing remains, then, but to give what relief is possible by treating symptoms. Thus far we have not been able to make

* P. S. —Up to the 9th of February ninety cases had been admitted into Bellevue Hospital. Of these, forty-three were males and forty-five were females. The other two were infants, whose sex was not reported. The ages of these ninety persons were as follows, viz.: Eight months, nine months, two years, four years, seven years, nine years, each one.

Between	10	and	15	years	11
"	15	"	20	"	8
"	20	"	25	"	10
"	25	"	30	"	11
"	30	"	35	"	15
"	35	"	40	"	15

any important additions to the suggestions just borrowed from the English and Scotch practice.

As destitution is regarded as one of the parents of the disease (although, as we have seen, it falls by force of contagion upon those who are well fed, well housed, and well clothed), we look to food and tonics, especially during the intermission, as the means by which strength may be gained to bear the relapse; and in the few cases in which there is threatening syncope in the defervescence, alcoholics will be useful. To "stamp out" the disease, as friend Harris expresses it, all persons, attacked in crowded and ill-ventilated quarters, must be sent at once to relapsing fever hospitals.

To Dr. Louis Sproat, in January, my House Physician, I am indebted for a transcript from the hospital records of the cases on which the last half of this lesson is founded, and still more for his care and intelligence in the investigation of the disease in that division of the hospital to which he is attached. Indeed it has greatly interested me to witness a total disregard of personal risk in all the House Physicians and their assistants, and the earnest devotion of all to scientific inquiry regarding the nature of this new foe to our country's welfare, and to the humane, may I not say holy, offices of the true physician.

Dr. Thomas J. Moon, one of the House Physicians, prepared for one of Dr. Flint's lectures a table showing the frequency of the most important symptoms of this disease in the three Medical Divisions of our hospital, including the cases reported in this lecture; from which I borrow the following:

No. of cases treated up to Feb. 15	.....	103
Jaundice noticed	"	9
Hepatic tenderness	"	18
Splenic "	"	11
Epistaxis	"	21
Nausea and vomiting	"	39
Diarrhœa	"	11
Eruption of some kind	"	5
Delirium	"	4
Bronchitis	"	6
Pains in calves of legs, knee joints and upper extremities	"	103
Pains in head and back	"	103
Constipation more or less	"	92
Convulsions	"	1

Dr. Moon finds two fatal cases in the 103. In one of them death followed suppression of urine, and in the other, referred to already, it occurred in syncope during the first defervescence. It is not right, however, to say that in our cases the mortality was less than two per cent.; because at the date of this report there were at least ten of those still under treatment in whom death was possible.

Dr. Moon counts under the head "Contracted Disease in Hospital" 12.

I may add that among all these cases there has been no instance of repeated relapse, and as yet no occurrence of post febrile ophthalmitis.

(In the next number will be issued a note by Dr. Clark regarding Dr. Dubois' cases.)

Library of the College of Physicians of Philadelphia.—The whole number of volumes in this library amounts to more than fifteen thousand, which is exclusive of 600 volumes of duplicates. These last are for sale.

The Peabody Memorial Hospital.—A site for a memorial hospital has been selected in Blackfriar's Road, London, by the trustees of George Peabody's estate.

CLINICAL LECTURES ON

THE DIAGNOSIS AND TREATMENT OF STRICTURE OF THE URETHRA.

By J. W. S. GOULEY, M.D.,

PROFESSOR OF CLINICAL SURGERY AND OF GENITO-URINARY DISEASES IN THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

Lecture I.

INSTRUMENTS FOR EXPLORATION OF THE URETHRA—DIFFICULT CATHETERISM—AN ILLUSTRATIVE CASE COMPLICATED WITH RETENTION OF URINE—DIVULSION WITH CONDUCTOR.

Dec. 8, 1869.—I propose, in a short series of oral lessons, with illustrative cases, to invite your attention to subjects the importance of which you will, perhaps, more thoroughly appreciate when you have experienced in your own practice the extent of the difficulties which sometimes attend catheterism. The surgical manœuvre which consists of introducing an instrument through the urethra into the bladder, either for the purpose of exploration or for the relief of retention of urine, is made light of by some of our brethren until they find it impossible, from want of dexterity and gentleness, to relieve the sufferers who are committed to their care. It is not till then that they realize the full extent of their responsibility.

You know how often we meet with aggravated cases of cystitis, and grave and incurable disease of the kidneys, which might have been averted by the proper surgical treatment of strictures, at first easily controlled by gradual dilatation; and how much oftener we encounter cases complicated with false passages, which are consequent upon forced catheterism, applied either designedly or through recklessness or ignorance in the use of instruments.

These circumstances have induced me to ask your indulgence and patience while I describe the various procedures which are required for the diagnosis and treatment of some of the affections which interfere with the flow of the urine through the urethra. The patient now before you, suffering from retention of urine, will serve as an additional excuse for my remarks, and at the same time will illustrate and enforce them. In undertaking the management of such a case, the duty of the surgeon is, first, to ascertain the cause of the retention of urine; secondly, to take proper means to relieve the over-distended bladder; and, thirdly, to resort to the safest and best method at his command to prevent recurrence of the trouble. To arrive at a correct diagnosis, it is necessary to take into account the previous history of the patient as well as his present condition, and to make a careful exploration of the urinary tract. Let us apply these principles to the case before us.

Case 1.—J. W. W. is a married man, thirty-three years of age, who has always enjoyed good general health; his build is that of a healthy man, but you observe that he has a pallid and bloated face, with some puffiness of his lids. He has long been addicted to the excessive use of ardent spirits. He has never passed any gravel, nor has he ever suffered any injury of the urethra; but he has had three attacks of urethritis,—the first, fifteen; the last, thirteen years ago; all uncomplicated and well in a short time, with the exception of the last, which was followed by a gleety discharge that has lasted to the present moment. Ever since the last urethritis, he has noticed a gradual but steady diminution in the volume and force of his urinary stream. He has also, for thirteen years, been troubled with irregular chills, which have become quite

frequent for the past three years. During the last-mentioned period he has had no regular jet, but has passed his urine guttatim with much straining and great frequency, often once every fifteen minutes. Strong drink always aggravates his trouble, and on several occasions, after debauches, he has had attacks of urethral hemorrhage. For the last four weeks the urine has dribbled from him constantly, day and night, save that twice within that space of time he has had complete retention, once lasting half a day, and once an hour and a half, relief coming spontaneously on both occasions. For the last four or five years his urine has appeared muddy and has contained a copious sediment, and at times has been alkaline. Latterly he has suffered much from pain in the hypogastric region, accompanied by a constant desire of micturition, which could not be properly gratified. He has also complained of shooting pains in the groins and thighs.

You have learned from the brief history just narrated that the patient has never suffered from calculous disease, and that the retention of urine came on gradually, not suddenly, as would have been the case if a calculus had lodged at the neck of the bladder, or in the urethra; therefore you will naturally exclude that, as you will also the presence of any other foreign body, as a cause of obstruction. You will also remember that he has sustained no injury of any kind to produce impediment to the flow of urine. If, moreover, you take into account his previous good health, his age, and the fact that his gonorrhœas were uncomplicated, you will as readily exclude obstruction from disease of the bladder or prostate. There only remains, then, for consideration, some morbid alteration of the urethral canal, and you will have every reason to look for this if you bear in mind that the patient has had repeated attacks of urethritis, the last followed by a persistent gleet, which is one of the prominent symptoms of stricture of the urethra. But as yet you have only had the patient's statement as evidence—very good so far as it goes, and of great assistance; but you must have something more positive, more tangible, on which to base a diagnosis. You should neither express an opinion nor venture to apply a remedy in such a case until you have thoroughly analyzed all its points, and have resorted to direct exploration of the urethra.

Let us first take a general survey of the patient, and then bring to bear the exploring instruments. You notice that this man's shirt is saturated with moisture, and if you were close enough, you would not fail to perceive the offensive urinous odor which emanates from his person. Notice also, if you please, the well-defined tumor which extends from the pubes up above the level of the umbilicus, and which, as you are now able to hear, is flat under percussion; this is the distended bladder, which must be relieved of its burden. You observe that the prepuce is abnormally long, red, and sodden, from the action of the constantly flowing urine. The perinæum shows no swelling, induration, or any other sign of rupture of the urethra. Another fact worthy of your attention is, that he does not now complain of any uncomfortable sense of distention in the region of the bladder; it is because this organ has been so long filled and is so much overstretched that it has lost its sensibility. It will be found, when the urine has been drawn off, that the bladder has, in a great measure, also lost its contractility. This investigation of the case will remain incomplete and unsatisfactory until mechanical exploration of the urethra has been resorted to, by which the most reliable evidence will be obtained. How is this to be accomplished? Which of the several methods is the simplest, readiest, and safest?

Be advised, and do not attempt to introduce a metallic instrument for the purpose of exploring the urethra in a case such as this one, for you will learn little, if anything, while you may do mischief to the patient; and I remember that if a full-sized instrument can be passed with ease through the whole length of the urethra, you must look for a cause of the retention of urine other than stricture of the canal.

Here is an instrument (Fig. 1) which you have frequently seen me use in this lecture-room; it is commonly known among us as Leroy d'Etiolles' "bougie à boule" (bulbous bougie); it is soft and pliable, with an "acorn-shaped" swelling at the extremity. When it is introduced into the urethra, and encounters even a very slight obstruction, it is arrested in its progress; but a little pressure will generally send it through the constriction with a jerk; if after a few moments an attempt is made to withdraw the bougie, the spasmodic contraction of the strictured canal,—there is almost always a certain amount of spasm in organic strictures,—by pinching the shaft just above the bulbous extremity, makes the withdrawal sometimes almost as difficult as the introduction; it can, however, be withdrawn with very little if any force. In this manner the situation, diameter, length, and number of strictures can be ascertained with tolerable precision. These bulbous bougies vary in size from No. 1 to the largest numbers in the scale, as you see from the set which is upon the table. You should always begin the examination with a good-sized one, and when gentle pressure fails to carry it past the obstruction you must substitute a smaller instrument, until the calibre of the constriction is reached.

FIG. 1.

The profession is indebted to Sir Charles Bell for the introduction of this mode of exploration; it is true that his instruments were not as perfect as those we now use, but the principle is the same. Bell's "ball probes," as he called them, were little hollow metallic balls soldered to the ends of wires. Leroy d'Etiolles has brought them to their present degree of perfection by modifying their shape, and having them constructed of soft, non-metallic material, which renders them superior to the original in every respect. It is curious that this English invention should have been little if at all employed by the English, after the time of Sir Charles Bell, till within a few years. Perhaps the best bulbous bougies are made in France; latterly, however, our instrument-makers have imported some pretty good ones from England.

Understand, if you please, that these instruments are only intended as explorers, and that they should not be used as dilators.

This bougie, which is six millimetres in diameter at the largest part of the bulb, corresponds to about No. 9 of the English scale.—You see that it readily enters the meatus, but is now arrested and will go no farther.—It is withdrawn to make way for a smaller one, and by measurement the obstruction is found to be situated one-third of an inch from the external orifice.—Here is another bougie, four millimetres and five-tenths in diameter, about equal to No. 6.—With very little pressure it has passed the stricture;—in withdrawing it and measuring again, it is found that the constriction is a quarter of an inch in length.

If you take into consideration the degree of permeability of the stricture which has just been explored, you will naturally conclude that it cannot be the real source of the retention of urine, and that there must be

another constriction farther back. The same instrument will therefore again be introduced;—it is arrested at a distance of four inches, and will make no farther progress.—I substitute the smallest bougie, but it only goes one inch farther back, and will not budge. It is not possible to estimate the length of this stricture, because the smallest bulbous instrument has only penetrated it for the distance of one inch, and cannot pass beyond; the narrowing may extend back another inch, for all we know. This man's urethra has become so narrow at the seat of disease, that less urine flows from the bladder than enters it, consequently the longer interference is delayed the greater will be the accumulation, and relief must come speedily or the bladder or urethra will burst.

Now that the diagnosis has been made, or, in other words, that the nature of the impediment to micturition has been ascertained, let us see what means can be contrived for the relief of our patient. An effort must be made to enter the bladder through the natural channel, without cutting, if possible; but in any event the urine must be drawn off.—Puncture of the bladder, either through the rectum or above the pubes, is at best but a palliative, as it does not remove the urethral obstruction, and besides it is by no means free from danger; it should therefore be rejected.

The methods of treating strictures of the urethra which are now most generally resorted to may be summed up as follows:—1. Dilatation; 2. Divulsion; 3. Internal Urethrotomy; 4. External Urethrotomy. *Dilatation* is usually tried first; if it fails *divulsion* is employed, except in obstinate strictures of the pendulous portion of the urethra or those near the external orifice, in which *internal urethrotomy* should be performed. *External urethrotomy* is demanded in severe contusions of the perinæum, where the urethra is almost always torn across; * in narrow unyielding traumatic strictures, in narrow resilient, and in impassable strictures with retention of urine; also for the relief of cases complicated with obstinate urinary fistulæ.

If the stricture in this case happens to be impassable to the smallest bougies, it can be reached by incision through the perinæum. But this must not be thought of until all attempts to get through it have absolutely failed. In order to facilitate the manipulations upon the deep-seated stricture, the constriction situated one-third of an inch from the external orifice should first be attacked. Experience has taught us that strictures situated at the meatus or in the fossa navicularis are not amenable to treatment by dilatation or by divulsion; in fact any such attempts made upon them are not only ineffectual, but result in greater subsequent contraction. These strictures are best treated by deep incision, which may be made with an ordinary bistoury, or with this concealed knife, which Civiale has called his "urethrotome à bascule." A little instrument closely resembling it was found in the ruins of Pompeii, and was probably used for similar purposes.

I shall introduce this "urethrotome à bascule," or "bistouri caché," and incise the stricture from behind forward along the floor of the urethra, and include the meatus in the incision, stopping only short of making a hypospadias, in order to allow for the contraction which will follow upon cicatrization.—You see that there is no longer any hindrance to the passage of the largest instruments. The hemorrhage is very slight, and will cease spontaneously. I am now ready to commence proceedings against the deeper stricture, and as it has been found exceedingly narrow, it must be dealt with accordingly. First, the urethra will be filled with oil, and then the smallest instruments, such as you see upon the table, will be employed.—Here are the little whalebone bougies, already so familiar to you.—From them I select a straight one, half a millimetre in diameter.—It will not go, as you see, very far beyond five inches.—It must be left *in situ*, that three or four more may be successively passed by its side.—But this does not seem to succeed.—Now this one, which is spiral at its extremity, will be tried.—It appears to enter the bladder;—it moves freely;—but I must satisfy myself that it has reached its destination. The others will be removed, and further exploration will be made with the finger in the rectum.—Pressure made with the point of the finger, in the direction of the posterior surface of the triangular ligament, prevents the instrument from being moved backward and forward. When the finger is withdrawn, you see how easily and freely it moves. This is a pretty satisfactory evidence that it has gone in the right direction. A very important fact is incidentally ascertained by this rectal exploration. It is, that the urethra is dragged upward by the distended bladder, which has become too large for the pelvic excavation, and has been forced up into the abdominal cavity after the fashion of the gravid uterus. What is to be dreaded from this circumstance? The urethra, whose course is greatly changed, has been put so much upon the stretch that even the slightest force would tear it across, or an instrument carried in with any degree of pressure would make a false passage, which would extend back between the prostate and rectum, where urine would escape and cause extensive pelvic cellulitis, with probably a fatal result You can therefore appreciate with what caution and gentleness such a case must be handled, and you see, from the difficulties just experienced, that it would, after failure of the usual modes of catheterism, have been considered as a case of impassable stricture, demanding either puncture of the bladder or external perineal urethrotomy without conductor; but with the method employed it will be made quite tractable. The most important and difficult step of the operation was accomplished when the slender whalebone guide-bougie or conductor was coaxed through the strictured portion of the urethra. This first step succeeding, the others will be comparatively facile. I know of no simpler or more effective mode of catheterism than this. When you have failed with the ordinary methods, have recourse to it, and I am sure you will seldom be disappointed. Always lubricate with oil the urethra instead of the instruments; I consider this essential to success. You should have in your case of instruments at least a dozen of these whalebone probe-pointed conductors, of the length of ordinary gum bougies, and about half a millimetre in diameter—equal to No. ½, or thereabouts, of the English catheter scale. Some should be straight, some spiral, some with the point bent at a little less than the angle indicated (Fig. 2).

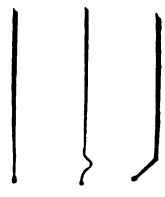

Fig. 2.

Now that the bladder has been entered by the guide-bougie, a little preliminary dilatation should, if possible, be made before attempting to introduce the retention catheter* (Fig. 3), which

* This operation was recommended by Reybard, under the circumstances above referred to, as a preventive of stricture. See his Treatise on Stricture, Paris, 1838, pages 76-80 and 81. More recently Prof. Boeckel, of Strasbourg, has popularized Reybard's views by presenting them in the form of an aphorism:—"Every transverse rent of the urethra is a stricture in embryo,"—and has also proposed and performed external urethrotomy as a preventive. See page 32 of his pamphlet, reprinted from the *Gazette Médicale de Strasbourg*, 1868.

* For a full description of the manner of using the retention catheter, see Medical Record, May 15th 1869.

is three millimetres in diameter, nearly corresponding to No. 3 of the English scale, and is conical, its point being two millimetres in diameter, about equal to No. 1 of the same scale. A groove on its convex side extends a distance of four inches, and is bridged over in its last twelfth of an inch, so as to form a canal for the reception of the whalebone guide. The catheter eye is on the concave side of the instrument, about three-fourths of an inch from its point, and is kept closed by a well-fitted stylet. Its curve is equal to one-fifth of the circumference of a circle three inches and a quarter in diameter.

Fig. 3.

This preliminary dilatation—sometimes divulsion occurs—is, I believe, best accomplished by the aid of this grooved steel staff (Fig. 4),—devised by me seven years ago,—two millimetres in diameter at its point, which is tunnelled for one-eighth of an inch. If the free end of the guide-bougie, which already occupies the whole length of the urethra, be passed through this tunnel or canal, the staff, as it advances, must follow the guide-bougie.*—The point of the instrument now rests against the face of the stricture; there it will be held firmly, but no force will be used. In a few moments it will probably pass the obstruction. If it should not, cutting should be resorted to without delay.—But you observe that it has made some progress.—It has entered the still more constricted portion of the canal, and has reached a point six inches from the external meatus. It will at once be replaced by a larger one (two and a half millimetres in diameter).—This also goes in.

Fig. 4.

—Now I am ready to introduce the evacuating catheter in a similar way, and, of course, with great caution, for it is necessary to pass that portion of the urethra which, as before remarked, is so much displaced as to be very easily injured.—You see that the urine is flowing through the instrument, but without force, for the bladder has lost much of its expulsive power; it must not, therefore, be completely emptied. This basin now contains three pints of urine, and, judging from the volume of the abdominal tumor, there is still probably the same amount in the bladder. This must be removed gradually, for the walls of the viscus have been too long overstretched to warrant its sudden evacuation. It may be several weeks before it recovers from its state of atony.

If the patient is left as he now is,—with the stricture but partially dilated, or rather only to a slight degree divulsed,—it will probably be impossible within twenty-four hours, owing to inflammatory swelling, to pass an instrument and draw off the urine, without running great risk of doing mischief. Therefore the wiser course to be pursued will be to enlarge the urethra forthwith at the seat of stricture, so as to facilitate the introduction of one of the largest sounds. You might ask, Why not treat the case by continuous dilatation? Why not, at least, tie in a soft catheter for only twenty-four hours? Either plan might be adopted under certain circumstances; but there is nothing, at present, to be gained by temporizing, and it is of such long standing as to demand immediate interference; besides, a longitudinal rent of the narrowest part of the strictured urethra has already been made by the conical instruments that have been passed, as shown by the slight hemorrhage which has occurred; and surely there is no additional risk to be run in enlarging that rent—why not do so at once and save time and trouble?

To effect this I shall resort to the method known as divulsion, a term that has long been in use in surgical parlance, but which seems to have only within a few years been employed (by Voillemier) in this connection. It is derived from the Latin *divello*, which means to pull asunder, to rend, and expresses rupture, laceration. It should be used in preference to the word rupture, which is generally employed in the sense of accidental laceration from external violence, as in injury of the perinæum, or of the giving way of the urethra behind the stricture, as for instance, "rupture of the urethra followed by extravasation of urine." The English surgeons still adhere to the terms "to rupture" or "to split" a stricture, and yet they name their instruments "dilators;" if the strictures are "ruptured," "lacerated," or "split," the instruments should be called rupturers, lacerators, or splitters, and not dilators. How much nicer the terms "to divulse," "divulsion," "divulsor." Be it understood then, when I speak of treating a stricture by divulsion, I mean that a longitudinal rent of the strictured portion of the urethra is made. This may be accomplished by the successive introduction of conical sounds, beginning with small ones, or by any of the various divulsors (improperly called dilators) which are in use. These are Perrève's instrument and its modifications by Holt, Richardson of Dublin, and Voillemier; Michéléna's and Sir Henry Thompson's, and their modifications. The simpler the instrument the better.

Here is one which I have modified from Sir Henry Thompson's pattern; its merits will be discussed at our next meeting, as there is scarcely time for this to-day. You see that it is constructed on the same plan as the instruments before introduced, having a short canal at its extremity,—the guide is now engaged in the canal, and the divulsor is being passed into the urethra, so that the portion of the instrument which is susceptible of greatest expansion may correspond as nearly as possible to the narrowest part of the stricture: this is probably about five and a half inches back. Now, observe how rapidly the expansion is being made;—this separation of the two longitudinal halves of the instrument can be effected very slowly or with great rapidity, at

* This method of catheterism is, I believe, an improvement on the old French mode of catheterism upon a conductor, devised by Desault, or on the method of Wakley, or the more modern device of Maisonneuve, which he names "cathétérisme à la suite," with a small gum bougie, which very often coils up in front of the stricture instead of entering it. This very flexible guide has been adapted by Maisonneuve to his urethrotome, and is very liable to be cut across by the blade of the instrument. Voillemier has also adapted it to his divulsor. Here again it has similar disadvantages, and will meet with very little favor. But the whalebone guide-bougie adapts itself admirably to the inflections of the urethra, and is applicable to the catheterism of strictures situated either in the pendulous portion or sub-pubic curve of the canal. I have sometimes used the fine English bougies as guides to the steel staff. They are stiffer, and therefore better than the French.

To facilitate the introduction of the evacuating catheter, I often dilate the strictured portion of the urethra by introducing successively over the conducting bougie two or three of the conical tunnelled staves, even if the constriction should be such as to admit the point of the smallest of the evacuating catheters. These steel instruments, being heavier, can be handled with more ease and safety than catheters. My set consists of four staves; the smallest (No. 3) is 1½ millimetres in diameter at its point, the second (No. 4) 2 millimetres, the third (No. 5) 2½, and the fourth (No. 6) 3 millimetres. Their curve is equal to one-fifth of the circumference of a circle three inches and a quarter in diameter: I have found a greater curve to be of decided disadvantage, as, in that case, the conductor constantly tends to slip away from the groove of the staff—in which it should always be lodged—and thus to render its introduction very difficult, if not impossible.

the option of the surgeon; sometimes it is best to operate slowly.

The divulsor has reached its greatest point of expansion, and the strictured portion of the urethra can now admit with ease No. 18 sound of the English scale. As the instrument is withdrawn you will perceive that its two segments are not completely approximated, they are in fact only half closed: this precaution had better always be taken, for sometimes, especially if the instrument is not carefully made, the urethra is pinched up between the closed segments, and in pulling out the divulsor a portion of the mucous membrane is torn away.

The hemorrhage, you see, scarcely exceeds a drachm. Observe, if you please, how easily this No. 16 sound slips into the urethra and enters the bladder. No anæsthetic has been used, because I thought it was necessary that I should be guided by the patient's sensations.* He was very nervous and irritable, his urethra was very sensitive, but he suffered more from anticipation than from the real pain. You will almost always succeed in managing such a patient to your satisfaction by kind words and a light hand. He will now be sent to bed, and the after treatment will consist of free doses of quinia, ten grains of which, with a quarter of a grain of morphia, will be given at once. To-morrow he will begin to take ten-drop doses of tincture of the chloride of iron. It is a mistake to give more than ten drops of this drug three times in the twenty-four hours; often I give but five drops at a dose. Many administer twenty or even thirty drops at a time, but this is a waste of material; besides it is very apt to derange the digestive functions, and to give rise to annoying constipation and other unpleasant disorders. His urine will be drawn at regular intervals until his bladder is quite emptied, and then the organ will be injected twice a day with tepid water, until it regains its power of contractility and the cystitis has subsided. Then once every third day a full-sized steel sound will be passed. Next week you will probably be able to examine the patient and see for yourselves the result of all that has been done to-day.

OBSERVATIONS ON THE ADIRONDACK MINERAL SPRING.

By JOHN BELL, M.D.,
PHILADELPHIA, PA.

Acting on the recommendation of Dr. Hanbury Smith, when he read his paper on mineral waters as therapeutic agents, before the N. Y. Academy of Medicine, as reported in the Medical Record, Nov. 1869, I submit a few observations on a recently discovered mineral spring called the Adirondack. If our therapeutics are to undergo a thorough and beneficial change by the substitution of a large class of active yet readily controllable medicinal agents, congenial with the wants of the organism, for drugs which are often harsh and irritating in their operation, and mischievous when not serviceable, we must have recourse to mineral waters. With them we can meet nearly every indication in the treatment of chronic diseases, and by judicious selection combat not a few of those of an acute character. The subject has always been one of deep interest to the present writer, and been often presented by him, under various aspects, in publications which need not now be named.

The Adirondack mineral spring was only discovered in the latter part of the year 1868. It derives its name from its flowing at the base of one of the spurs of the Adirondack mountains. The spring is situated in the village of Whitehall, in the northern part of the State of New York, at the head of Lake Champlain. An analysis by Professor Colyer, of the University of Burlington, Vermont, gives the following proportion of ingredients contained in an imperial gallon of the water:—

	Grains.
Free Carbonic Acid	67.257
Carbonate of Lime	18.543
" Magnesia	16.618
" Potash	5.317
" Soda	5.040
" Lithia	.023
" Iron	5.040
" Manganese	traces.
Chloride of Sodium	14.340
Sulphate of Lime	11.134
Alumina	traces.
Silica	.742

Iron is contained in the Adirondack water in larger proportion than in most of the mineral springs; potash, in very appreciable quantity in it, is rarely met with beyond a mere trace in others.

Were we to speculate on the probable effects of the Adirondack water deducible from its chemical composition, we might be led to believe in its serviceableness as a tonic, an acid and genial stimulant, in various disorders of the digestive and renal apparatus, and of the skin; but we prefer telling at once what experience has thus far revealed of its therapeutical value. This water is clear and colorless, and of a taste slightly chalybeate, conveying no adequate idea of the strength of its mineral impregnation. After a time it shows a yellowish deposit, which, by agitation of the bottle holding it, is redissolved. Its first most marked and decided operation is on the kidneys, as a diuretic; occasionally, when taken fasting or on an empty stomach, to the extent of a pint, it acts as an aperient. The common dose is half a pint three times a day, and when continued for a length of time half of this quantity. Like so many mineral waters, it sometimes affects the head with a feeling of tension and slight dizziness.

The concurrently favorable opinion, expressed by the physicians of Whitehall, of the efficacy of the Adirondack water in serious renal disorders and chronic rheumatism, has been confirmed by the experience of medical gentlemen of Philadelphia. Dr. D. H. Agnew employed it with the most satisfactory results in the case of a man suffering under symptoms of stone, and with albuminous and bloody urine, which last was very scanty. The urine had become ropy and offensive, notwithstanding the use of all the ordinary diuretics. Recourse was now had to the Adirondack water, and "in thirty-six hours the urine became copious and soon free from mucus, and washed out two calculi, the size of a coffee-grain each." Prompt relief and a speedy cure were procured for another patient with albuminous urine and defective renal secretion, after she had been confined to her room for several weeks under the usual treatment. In a case of rheumatism under the care of Dr. Agnew, the water excited such a free secretion from the kidneys as to require it to be continued in small doses. This gentleman has also described to me another case, one of nephritic colic, with scanty and bloody urine, in which the water was taken with equally prompt result as in the other cases, and shown by the discharge of a large-

* In only one instance, out of many operations, have I been obliged to administer an anæsthetic.

sized concretion. Dr. Agnew thinks there can be no doubt of the powerfully diuretic property of the water. In a case supposed to be one of a retention of a calculus in the pelvis of the kidney, for which he ordered the water, such was the profuse flow of urine in consequence that the patient was obliged to desist from its use, owing to his being so much disturbed at night. Dr. E. Wallace regards the water as superior to any of our known diuretics; and in a case of pleural effusion, with partially solidified lungs, under the care of Dr. Da Costa and the writer, in which different diuretics had been directed by them without success, eventually recourse to the Adirondack water was followed by copious renal secretion and much relief to the patient, whose appetite also was improved by the remedy. Other instances of its actively diuretic operation could be cited by the writer. Dr. Wallace relates his having obtained a complete cure of a person who had suffered greatly from subacute rheumatism, affecting particularly one knee, and from excessive prostration. Giving the water at the same time with other remedies, he found that when it was discontinued the renal secretion became immediately impaired, but was soon restored and increased by recourse to the use of the water. Dr. Shumway of Whitehall regards its general effects to be stimulant, tonic, and diuretic; in excessive doses producing headache, giddiness, gastric oppression, and irritation of the urinary organs. "In proper medicated doses it promotes digestion, increases the flow of urine, gives tone to the capillary vessels of the skin, and is a healthy stimulant to the secretory and excretory organs generally." Enough is known of the properties of the Adirondack water to prompt its use in atonic dropsy and in an anæmic condition of the system, so often represented in chlorosis, leucorrhœa, and amenorrhœa, and associated with chorea, hysteria, and hypochondriasis. There is reason also to believe in its curative powers in certain forms of dyspepsia, cardialgia, and pyrosis, and in diarrhœa and torpor and congestion of the liver. Drs. Bennett and Ling, of Whitehall, cite each a case of diabetes mellitus cured by this water. One of the patients under its use gained fifteen pounds in weight in four months. From the quarter just mentioned we learn instances of gravel speedily and permanently relieved by drinking the water, and others of difficult and painful urination, and even complete obstruction, yielding to the same remedy. Its curative powers have also been displayed in some obstinate cutaneous affections of the vesicular and squamous kind.

Progress of Medical Science.

Oil of Sandal-Wood.—Dr. Park, of Stanmore, England, states, in the *Practitioner*, that after twelve years' experience with the oil of yellow sandal-wood, he is convinced that it is the safest and most reliable drug we possess for the cure of blennorrhagia. He administers five minim doses every four hours.

Hypodermic Use of Ergot in Pertussis.—C. T. Deane, M.D., Phys. to S. F. Female Hospital (*Cal. Med. Gazette*), has used ergot hypodermically in an obstinate case of pertussis, and is much pleased with the result. He employed the watery extract according to Beaujean, and injected it in the arm every other day for eight days.

Treatment of Eczema.—Dr. Erasmus Wilson, F.R.S. (*Jour. of Cutaneous Medicine*), after endeavoring to show in the treatment of eczema, that the patient needs repose, quiet, rest, and proper and nutritious food without stint or limit, asks: "What else is to be done? Shall we purge or physic the patient? God forbid. If the bowels are confined, help them with a little magnesia and rhubarb, or manna, or castor-oil; if the patient is emaciated, and exhibits a tendency to waste, the prostration may be checked by cod-liver oil; but the one and almost indispensable remedy is the nerve-restorer, arsenic. Try two minims of the liquor arsenicalis three times a day in the following combination:—℞ Vini ferri, ℥ iss.; syrupi simplicis, ʒ iij.; liquoris arsenicalis, ℥ i.; aquæ anethi, ℥ ij. Misce. One drachm will give two minims of liquor arsenicalis. It may be administered pure, and just at the end of the meal, so as to be mixed with the meal in the stomach. The physician should watch narrowly the arsenical solution to see that it occasions no nausea, no gripes, and no prostration of power. These are its primary effects when it disagrees with the system, and there are sundry subsequent effects, such as a puffy swelling of the eyelids, the cheeks, or limbs; and later still, congestion of the vessels of the conjunctiva."

Calomel an Accelerator in the Evolution of Teeth.—According to M. Champonillon (*Missouri Dental Journal*), calomel accelerates the evolution of the teeth in the first dentition. He cites *two* (!!) cases confirming his views.

An Epidemic of Hemeralopia in the Strasbourg Garrison.—Médecin-major Poncet communicates to the editor of the *Gazette Hebdomadaire* (No. 29) an account of an epidemic of hemeralopia which occurred at his garrison during the months of May and June last, principally in members of the 18th and 96th regiments of infantry. Thirty of these cases were daily submitted to independent ophthalmoscopic observations, and the result of the examination recorded.

Animal and Human Vaccine.—In a recent discussion in the French Academy of Medicine, published in the *Gazette Hebdomadaire*, M. Guérin reviewed the evidence for and against animal vaccination, and came to the conclusion that there was an essential difference between vaccine obtained directly from the heifer and human subject. The latter he believed to be much more active and reliable, and, in fact, a different principle resulting from two elements—one human and one animal. He questioned very seriously the propriety of banishing human vaccination from the public establishments in order to substitute animal vaccination in its place.

The Uses of Ergot.—Dr. J. W. Curran gives the following as his experience with ergot of rye in diseases for which it is not usually prescribed:—

Hæmoptysis I have frequently arrested for a time with ergot, with good effect in the commencement of phthisis; but I should not be disposed to prescribe it, lest vomiting should be set up in the hæmoptysis which sometimes accompanies the advanced stages of pulmonary consumption.

Hæmaturia.—I have found great benefits from the tonic effects of ergot upon the blood-vessels, in causing a diminution of their calibre, and arresting hemorrhage from the kidney. I can safely say that its effects are superior to either turpentine or the vegetable acids in this complaint, and that the same observation applies to the tonic effect it produces on the muscular fibre of the bladder in those cases of general atony which come under our notice, and for which so little permanent good can be done.

Constipation of the Paralytic is strikingly remedied, when the most powerful cathartics fail, by occasional

doses of ergot, which sensibly diminish the amount of blood present in the spinal cord and its membranes, give tone to the muscular fibre of the bowels, and thus propel the fæcal matter to the rectum.

Fatty Degeneration of the Heart.—I have had and still have two patients suffering from this complaint, who are very materially assisted by occasional doses of ergot. I can only compare its tonic virtues to that of carbonate of ammonia, but as experience is limited I cannot write emphatically.

As an Injection in Gleet.—I believe I have been the first to use the infusion of ergot in this complaint, and I have not yet failed. I employ the pharmacopœia infusion, and direct its being injected three and four times in the day. I observe the tonic power it imparts to the urethra.

When the injection is thrown along the urethra, I direct the meatus urinarius to be firmly pressed against the nozzle of the syringe, so that the ergot may lie for five minutes in the urethra; for experiment has taught microscopically that the effect of ergot locally applied to a raw surface is, 1stly, to increase the circulation; 2dly. to suspend the circulation; 3dly, the circulation recovers itself, is still disturbed and irregular, or spasmodic, showing that the contraction and relaxation of the muscular coats of the arteries are subservient to the will of the ergot, hence undue contraction producing gangrene. These series of phenomena upon the blood-vessels of the urethra at all events set up healthy action and cure a foul disease.—*Medical Press and Circular.*

An Improved Apparatus for Fracture of the Inferior Maxillary Bone.—Wm. G. Bullock, M.D., Prof. of Surgery in the Savannah Med. College (*Am. Jour. Med. Sciences*), has invented an apparatus for fracture of maxillary bone, which for lightness, adaptability, simplicity, and convenience, he claims is superior to Lonsdale's, or any of those figured in *Hamilton on Fractures* or in Wales' *Mechanical Therapeutics.* This instrument consists, like that of Lonsdale, of a grooved plate or dental splint made of ivory, metal, or vulcanized india-rubber, accurately adjusted to the teeth or alveolar (by first taking an impression of the jaw, as is done by dentists, in wax, gutta-percha, plaster of Paris, or some pliable substance), to which grooved plate are welded projected arms of stout iron wire, about opposite the bicuspid teeth, arched so as comfortably to project out of the mouth without interfering with the lips. The ends of the projecting arms are bent to form holes through which pieces of cord, thread, or wire, are passed to attach the dental splint to a piece of wood, say a portion of a cigar-box cover, for a chin-piece, placed under the jaw, serving the purpose of a submaxillary splint. This latter should have four holes in it, two on either side, to make it more secure. This comprises the entire apparatus, and is applied to a fracture of the lower jaw, whenever the fracture is in the body of the bone, by fitting the dental splint to the teeth, placing a compress of patent lint or some soft material between the under surface of the chin and the submental splint, then tying the tails of the thread, or twisting the wire passed through the holes in the latter splint to the projecting arms of the former, thus doing away with the necessity of bandages over the head altogether.

Ligation of External Iliac Artery for Elephantiasis.—Hueter (*Arch. f. Klin. Chirurgie*) recently ligated the external iliac artery of a girl of 23, who was afflicted with *Elephantiasis Arabum.* Her left lower extremity had gradually attained an enormous size, from the toes upward, without the supervention of erysipelatous attacks. The peritonæum was left intact. The skin of the leg was soft, and could be lifted in folds eight hours after the operation. The wound healed kindly. The following decrease in size was noticed:—

	May 9th.	May 30th.
Circumference above the malleoli,	46 ctm.	26 ctm.
" middle of the leg	52 "	35 "
" knee	50 "	36 "
Greatest circumference of thigh	71 "	56 "

The patient is now under treatment, and the size of the limb is constantly decreasing.

The operation has been done, including this case, fourteen times; a cure was attained in nine cases, improvement in three. The subjoined arteries have been ligated for elephantiasis: The femoral nine times, the carotid once (on both sides), tibialis anticus once, the iliac twice.

Powdered Camphor a Dressing for Chancres.—M. Champouillon (*Recueil de Méd. et Chir. Militaires*) recommends a dressing of powdered camphor in primitive chancres, whether soft or indurated. In ordinary cases cicatrization occurs in ten or twelve days. This application is best adapted to chancres of the fossa and of the upper part of the glans, and internal face of the prepuce.

Case of Recto-Ischiatic Fistula.—A case of *recto-ischiatic fistula* of unusual interest is published in the *Transactions of the Penn. Med. Society*, by D. W. Bland, M.D., of Pottsville, Pa. A married lady, æt. 42, subject to hepatic colic and biliary calculi, was alarmed at the passage of fæces per vaginam, and upon examination not only a recto-vaginal fistula was found, but a very large fistulous sinus leading from the rectum some four inches deep into the glutei muscles. The index-finger could easily be passed into this sinus. The patient was placed upon general tonics, and an injection of carbolic acid gr. x., glycerine f℥j., aqua f℥ij., was directed to be used morning and evening. This treatment was persisted in for five weeks, with most gratifying success. The deep sinus closed up entirely; the vaginal opening is now restricted to a very small size. She has effectually recovered, and is now able to perform her household duties.

Hypodermic Injection of Morphia in Nausea and Vomiting.—Dr. T. V. Hammond, of St. Louis (*Med. Archives*), relates a case of vomiting and nausea, occurring at the period of menstruation, in a girl of 17, who was immediately relieved by the hypodermic injection of morphia.

Sulphite of Soda in Scrofulous Otitis.—Chas. M. Watson, M.D., of Brookville, Pa. (*Am. Jour. Med. Sciences*), finds the subjoined solution an invaluable remedy in scrofulous otitis:—Sodæ sulphit., ℈ij.; aquæ destil., glycerinæ, ää ℥ss. The ear should be well washed out with warm water and castile soap, and dried with cotton wool, after which 8 or 10 drops of the solution may be dropped into the canal and the air excluded with a pledget of cotton. This should be repeated thrice daily as long as the ear discharges.

Face Presentations.—Isaac E. Taylor, M.D., physician to the Bellevue and Charity Hospitals (*N. Y. Med. Jour.*), in a voluminous paper "On the Spontaneous and Artificial Delivery of the Child in Face Presentations, with the Chin Posteriorly," concludes his remarks by the following propositions:—

1st. That mento-posterior positions of the face are the most frequent; that spontaneous delivery may be accomplished as easily, readily, and safely as in mento-anterior cases; though the face has descended

into the excavation, the rotation of the chin forward to the pubes can occur, and sometimes just as the child appears to be born. 2d. That these cases may be delivered spontaneously by cephalic version in the pelvis, and by the passing also of the child's face over the perinæum, the chin appearing first. In other cases, the occiput may emerge from under the pubes *first*. 3d. That if rotation of the chin anteriorly cannot be accomplished naturally, nor by artificial resources, he proposes, first, the *division of the perinæum laterally*, on whichever side the chin presents, and before craniotomy is performed. 4th. Should the natural powers of the uterus not effect delivery, even after division of the perinæum, the application of the long *straight* forceps should be resorted to in preference to the curved, and the direction of the traction should be made directly downward and backward.

Contractility of the Lungs—Relations of the Pneumogastric Nerve to Respiration—An as yet Unnoticed Cause of Sudden Death.—A note of M. P. Bert was recently presented to the Parisian Academy of Medicine, by M. Claude Bernard, of which the following summary appears in the columns of the *Gazette Médicale de Paris* (p. 491):—

Pulmonary Contractility.—The experiments performed by the author permit him to affirm that the lung tissue is contractile, and that its contraction takes place under the influence of the pneumogastric nerve. He employed the graphic mode of investigation to prove this. The air which the contraction of the muscular fibres of the bronchial tubes expelled from the lungs raised a lever, and the trace furnished by this lever thus afforded the proof of this very contraction.

Influence of Excitation of the Pneumogastric Nerve upon the Respiratory Rhythm.—It is known, ever since the experiments of Messrs. Traube and Claude Bernard, that the electric excitation of the central portion of the pneumogastric nerve arrests the respiration instantaneously. But the greatest uncertainty prevails as to the phase of respiration during which this arrest takes place. Traube, Bernard, Snellen, and others, say it occurs in the inspiration. Budge, Eckhard, Owsjannikow, and others, maintain that it takes place in expiration.

More recently, Rosenthal believes that he has established the fact that the excitation of the pneumogastric nerve arrests the respiratory movements in inspiration by contraction of the diaphragm and the other inspiratory muscles. But, according to him, excitation of the superior laryngeal nerve produces an inverse effect—that is to say, an arrest in expiration by relaxation of the diaphragm, and tetanization of the expiratory muscles.

The numerous observations of the author, whose exactitude is guaranteed by the graphic traces, permits him to formulate the following conclusions:—

1st. Respiration may be arrested by excitation of the pneumogastric nerve, the superior laryngeal nerve, and the nasal branch of the sub-orbital nerve.

2d. This arrest may take place in expiration or in inspiration, by means of any one of these nerves, without the apparent intervention of a derived current.

3d. A feeble excitation accelerates the respiration; a stronger excitation retards it (and this for all the centripetal nerves); a very strong excitation arrests it (specially to the nerves above mentioned). These words, *feeble* and *strong*, have but a relative sense for a given animal, and in given conditions.

4th. When the respiratory movements are completely arrested, so are the general movements of the animal, which remains immobile.

5th. The respiration returns during the same excitation.

6th. It is easier to obtain arrest of expiration than of inspiration, and there are even animals in which it is impossible to obtain the latter.

7th. If we employ a very powerful excitation to arrest the respiration in inspiration, we may cause the respiratory movements (inspiration, demi-expiration, expiration) to cease instantaneously the moment the excitation is applied, and that whether acting on the pneumogastric or on the laryngeal.

Sudden Death by Excitation of the Pneumogastric Nerve (Central Portion), of the Inferior Laryngeal Nerve, or of the Nasal Nerve.—When the excitation of these nerves is sufficiently energetic it may determine a sudden death without convulsions; respiration and the general movements of the body are immediately arrested, and the animal dies as if struck by a thunderbolt. M. Bert has thus obtained the death of mammifers and birds, particularly ducks,—an important fact, for the suddenness of death with ducks shows that it is not due to an asphyxia (ducks resist asphyxia from eight to fifteen minutes).

It is due probably to a cessation of action, a *sidération*, by too strong centripetal excitation of that respiratory centre, of which the name *vital knot* seems, in part, justifiable.

Removal of a Shawl-pin by Tracheotomy.—In May last Dr. J. C. Reeve, of Dayton, Ohio (*Am. Jour. Med. Sciences*), removed from the trachea of a little girl, eight years old, a shawl-pin three and a quarter inches in length, by the operation of tracheotomy. At the end of forty-eight hours after the operation she was out of danger, and her convalescence was uninterrupted.

Sulphuret of Potash in Hooping-cough.—Dr. McLean of Hamilton, Ont., has used this drug with great success in this disease, in doses of a grain for each year up to four years of age, and after that half a grain additional for each year; the smaller doses being given in a teaspoonful of fluid, and the larger more diluted. Its beneficial effects are not perceivable for five days, when the interval between the coughs becomes longer, and after that their violence diminishes from day to day, until at the end of ten or fourteen days it is seldom necessary to pursue the treatment further.—*N. Y. Medical Journal.*

Removal of a Hair-pin from the Uterus.—Dr. Haine relates the case of a woman, who, thinking she had disease of the womb, had introduced a hair-pin, which slipping from her fingers had entered the uterus, where it remained. The finger, speculum, and the first trial of a catheter in the uterus revealed nothing. The woman insisting that the hair-pin entered, bent end foremost, a second trial with a catheter was made and the hair-pin discovered. By good fortune both legs were caught in the forceps, and the pin readily withdrawn.—*Pacific Medical and Surgical Journal.*

A Case of Labor with Varioloid.—Dr. Elstun reports the following case to the *Cincinnati Lancet and Observer:* A lady was taken in labor during an attack of varioloid which had come on about five days previous. The pustules were fully developed and were quite abundant all over the body. The labor was somewhat tedious, lasting about 18 hours. The child was strong and healthy, and was vaccinated on the following day, it nursing from the breast and sleeping in the same bed with the mother. The vaccination took nicely by the fifth day, and the patient escaped varioloid.

THE MEDICAL RECORD.

CASH PAYMENTS FOR MEDICAL SERVICES.

THE "Almighty Dollar" has its attractions for every class of individuals, high or low, rich or poor, reputable or disreputable, learned or unlearned. Although by a few it is considered in its plentiful possession as secondary to many other things, no one refuses to take care of it when thrown in his way. Every one recognizes in it a talismanic power for good in securing almost everything we may covet, either as luxuries or necessities. The hard-worked physician is not by any means to be left out of the catalogue, and with the rest of mortals is compelled to look upon the possibility of its more rapid accumulation with the keenest interest. Despite his love for science, investigation, experiment, and invention, his experience has taught him the intensely practical lesson that the actual necessities of his physical being depend solely on the amount in his money bag, or the extent of his bank deposit. He may study his profession for pleasure, but he must practise it for money. The greatest minds in the profession have not been insensible to this truism, and have always been compelled to sacrifice science to pelf.

John Hunter had to leave his study more than once for his guinea-fee, and very few at the present day are above such a necessity. We need not, however, enlarge on this point; our purpose at present is not so much the discussion as to the way we have to earn our money, or the necessities which drive us to it, but to the difficulties we encounter in collecting our fees. It is generally estimated that from forty to fifty per cent. of the physician's earnings are swallowed up in good promises and bad debts, a condition of things due almost entirely to the prevalent credit system. Is it not time that there should be some change for the better with us? Every practical business man has long since learned that the only true basis upon which pecuniary success can rest is the cash principle; and why, we ask, is there such a reluctance on our part to profit by this experience? There is no calling which, from the peculiarity of the services rendered, makes prompt payment more imperative. We come to the patient in his dire extremity, we relieve him, and not unfrequently save his life by our direct ministrations, at a time, too, when he is most grateful for the services, and consequently most willing to remunerate us. If, on the other hand, a credit follows, his desire to repay lessens in a direct proportion to the time which elapses, until finally it vanishes entirely.

> "Three faces wears the doctor: when first sought,
> An angel's—and a God's, the cure half wrought;
> But when, that cure complete, he seeks his fee,
> The Devil looks then less terrible than he."

Illustrative of the same truth is a story told by Jeaffreson, of Bouvart. On entering one morning the chamber of a French marquis whom he had attended through a very dangerous illness, he was accosted by his patient in the following terms:—

"Good day to you, Mr. Bouvart; I feel quite in spirits and think my fever has left me."

"I am sure it has," replied Bouvart dryly. "The very first expression you used convinces me of it."

"Pray explain yourself."

"Nothing is easier. In the first days of your illness, when your life was in danger, I was your *dearest friend;* as you began to get better, I was your *good Bouvart;* and now I am *Mister Bouvart;* depend upon it, you are *quite* recovered."

The affection which naturally is shown by the patient to the physician when the former is *in extremis*, is, in the abstract, refreshing and encouraging, but it would be more so if the poor sufferer could think so beyond the time when he has got all he wants in the shape of treatment. If human nature is so perverse as not to allow the fulfilment of these conditions, the physician must not be blamed for protecting himself and acting as much as possible on the maxim, "accipe dum dolet." The same idea is more elegantly expressed by the Scotch bard when he says:

> "Take the fee
> While the tear is in the ee."

Another strong reason for insisting on cash receipts is found in the rapidity with which money changes hands in this country. Fortunes are not unfrequently made and lost in a day, and the patient who may be abundantly able to pay our fee to-day, may be a bankrupt to-morrow. When the latter is the case, the physician is the most insignificant among the creditors, the last on the list for a compromise. Again: The migratory character of the people in this country is a powerful argument in favor of prompt collection. Our floating population is larger than that of any civilized country. Every year, and not unfrequently every month, the furniture truck is at the door of these nomads, and in the course of the succeeding twenty-four hours not a vestige of their previous sojourn is left. There are not unlikely many discomfited creditors in the background, but most certainly among these will be the neighboring doctor who succeeded in "raising our Johnny from scarlet fever," or who "brought our Jennie into the world."

The benefactor is either paid by a benediction for conscience' sake, or else is laughed at as a fool.

In a commercial community such as ours, a man's ability is measured more by his business tact than his brains. The physician who does not appreciate the truth of this will certainly be the loser. If we leave the impression upon the mind of our patient, that money is a secondary object with us, he will make it a tertiary one with himself. If it is of no consequence to us, how should it be to him? The very natural conclusion to which he must arrive is, that we are not particular about our cash, simply because our services are virtually worth nothing. Everything with business men, and with all classes, has its value in accordance with the business-like way in which the said value is fixed.

We have ourselves to blame after all, not only for the prevalence, but the continuance of the credit system. It is a peculiarity of the American medical profession. In no other country is it tolerated as with us. Practitioners in London and Paris, for instance, are, almost without exception, paid as soon as the visit is made, and most certainly when the patient is a stranger. The fee is handed them before they leave the house, and it comes just as natural for the patient's family to do so as to pass the time of day. In consequence of this the custom has grown upon these gentlemen to carry their money-bags with them in their carriages, in order to do away with the uncomfortable accumulation of guineas and francs about their persons!

We must own that our transatlantic friends have reduced the fee question to a science; and while making this acknowledgment, we have no right to say that they have thereby suffered in the estimation of the people. If we hold that such a practice is wrong, then the leading practitioners of Europe are nothing but a set of tradesmen. We can, after all, only make this difference between them and ourselves: they want the money, make an honest confession of such want, and then take it; while we want it perhaps more than they, are ashamed to have it known, and still more ashamed to take it. We allow a false delicacy to rule us, and designing patients take advantage of it. Practically it has come to this: if, in a majority of cases, we do not demand our fee at once, we will never get it. If the patient is made aware that our rule is prompt payments, he will contrive in some way to comply, and if not, the sooner we rid ourselves of him the less will we do for him for nothing. When we desire to work for charity, there are plenty of dispensaries and hospitals to which we can devote our time and understand what we are doing it for; but no stranger should have the presumption to enter our office and seek advice under the garb of a pay patient unless he has our fee in his pocket.

One of the great disadvantages of the credit system, not only to the physician but the creditor, is the apparently enormous amount which in the course of time accumulates, disposing the former to reduce it below what it should be, and scaring the latter into a total inability to pay any of it, except a still farther extension be granted. Both may be well meaning, but each does an injustice to himself. The chance is in the end that the physician not only is not paid, but loses what under the other rule would be a good patient. It is better policy for the sake of cash to accept from the majority much less than our usual charge than afterwards run the risk of collecting it when it gets on our books. The risk of losing it altogether is certainly fifty per cent., added to which are the expenses of the collector, the compromises, and the annoyances of constantly hoping against hope. A name may be good for any amount, but by being simply on our books cannot pay our debts.

The cash system is beginning to be adopted by many of our leading practitioners with the best of results. With many it is a rule strictly enforced, that no stranger comes to the office a second time, and that no strange family is visited more than once unless the required fee is paid. Experience has proved that the patients who are of the proper sort make no objection; in fact, rather prefer that it should be so. Every gentleman who chooses to adopt the plan will corroborate this statement, and will be surprised at the small number of exceptions that are necessary to be made to the rule. The want of a system of prompt payments is one of the main causes why the medical profession of this country are so poor. It is with the majority comparatively easy to make round incomes on their books, but it is exceedingly rare to find that these amounts can be balanced with cash. We cheat ourselves into the idea of prosperity by counting up our figures instead of our money. With few exceptions, none have made fortunes in this country by the practice of medicine, while the contrary is not a very uncommon thing with our confrères of Europe. No medical man in this country can claim an average income of one-half what Sir Astley Cooper or Sir Benj. Brodie obtained years ago; neither can they approach the sums that have been accumulated by Dupuytren, Velpeau, Trousseau, and Jobert de Lamballe. It does not appear that the charges made by these gentlemen averaged proportionately higher, all things considered, than those made by equally prominent practitioners in this country; neither can it be shown that the cash system reduced their receipts.

New Mount Sinai Hospital.—This new Jewish Institution is to be erected on Lexington Avenue, between Sixty-sixth and Sixty-seventh streets. Although this hospital was established by the Jews, it has always taken care not only of Jewish patients, but of those belonging to other denominations as well. During the past 3 years, over 50 patients who had met with accidents on the Hudson River Railway alone had received medical and other attendance at the Institution, and that of this number only one was an Israelite.

Three hundred thousand dollars are required to erect the building, and of this amount $50,000 have already been subscribed, by such men as A. T. Stewart, Peter Cooper, Benjamin Nathan, Wm. Butler, Duncan, Fisk & Hatch, and others—representing all religionalities.

Reviews and Notices of Books.

A Manual of Clinical Medicine and Physical Diagnosis. By Thomas Hawkes Tanner, M.D., F.L.S., pp. 366. Third American Edition. Philadelphia: Henry C. Lea, Publisher. 1870.

This practical manual has been for a long time out of print. The task of preparing a second English edition has been assigned to Tilbury Fox, M.D., London, Physician to the Skin Department in University College Hospital, who has enhanced the value and popularity of the work by adding much new matter with which every student and practitioner should be conversant. It contains an account of the clinical examination of persons for life insurance, and points connected with medico-legal investigations, which are alone worth the price of the work.

The proper mode of using the Laryngoscope, Ophthalmoscope, Sphygmograph, and Thermometer, is a new and noticeable feature of this edition. The last chapter, "On the Chemical and Microscopical Examination of the Blood, Expectoration, Vomited Matters, and Urine," is full of interest, the author having consulted the best authorities on these subjects.

The indistinct type and inferior paper do not reflect much credit on the American publisher.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 9, 1870.

Dr. Jos. C. Hutchison, President, in the Chair.

(Continued from page 20.)

Thrombus of the right subclavian artery and sudden occlusion of the left subclavian by the free extremity of the clot being forced into it by the current of blood.

Dr. S. Fleet Speir exhibited a specimen of above with the following history:—Mrs. H——, age 41, admitted to the Brooklyn City Hospital—service of Dr. H. S. Smith—Jan. 13, 1870. About four months ago she was taken suddenly on the street with pain in the region of the heart and shortness of breath; she was carried home and recovered from severe symptoms in about three weeks, there always remaining a considerable amount of dyspnœa, which was increased every three weeks. During most of this time she has had to sit up all night on account of the difficulty of breathing. The patient was greatly emaciated. There was dulness at the lower part of the right side of the chest—left side resonant, crepitant râles on the right side, and fremitus increased. Pulse 92, weak and intermittent—a beat lost in every six. The patient has not menstruated since she was taken sick. She has had three children.

Jan. 17. Pulse 100; temperature 98°. There are spots of purpura on some parts of her body—especially the extremities.

Jan. 31. There was noticed to-day, for the first time, a swelling of a bluish color and œdematous character low down on the left side of the neck, and also of the left arm and hand. The swelling of the hand and arm commenced at 9 A.M., and at 1 P.M. the tumor of the neck was noticed. The swelling of hand and arm, and also of the tumor, pits on very deep pressure. There is no pulse to be found either in the radial, brachial, subclavian, or carotid arteries of the left side.

Feb. 2. The tumor in the neck has decreased somewhat, but the swelling of the arm has increased. Patient died from asphyxia to-day.

Post-mortem examination (made by myself) about ten hours after death. Abundant sub-arachnoid effusion and serum in all the ventricles of the brain. Two points of peripheral apoplexy on left anterior and middle lobes of the brain; œdematous condition of the brain substance; cystic degeneration of the pineal gland. Between the muscles of the anterior part of the neck there was a purulent infiltration extending to a considerable distance on each side of the median line and low down on the right side of the neck; all the veins of the right side of the neck were distended with coagulated blood. There was a considerable enlargement of the thyroid gland. The *thymus gland* was also much enlarged, being of the size of an English walnut, flattened a little. The veins of the right side contained no clotted blood. The brachial artery contained a very small, thin clot about one inch and a half in length. But the vessel was not occluded by it; the subclavian artery was free from clot. Heart: masses of broken-down clot were found lying loose in the right ventricle and also firmly attached to its wall and imbedded in the meshes of its muscular structure. A large thrombus was found in the left subclavian artery, not entirely filling its calibre, but extending into the innominata and aorta, its large extremity passing across the upper part of the aorta and entirely filling up the orifice of the right subclavian, and the side of the clot obstructing at the same time the left carotid. Thus the clot, originally of the left side, was prolonged by the current of the blood into these vessels of the right side, and caused a complete obstruction to the circulation through them. The clot on the left side did not entirely occlude the vessel. The left lung was found adherent to the pleura in some places—otherwise healthy. The right lung was the seat of encysted empyæma. From the appearance of the interior of the artery and the clot, as well as the surrounding purulent infiltration, it was supposed that the thrombus in this case was due to arteritis.

The Society then adjourned.

Stated Meeting, February 23, 1870.

Dr. Joseph C. Hutchison, President, in the Chair.

Sudden death from obscure causes.

Dr. Finnell exhibited four specimens, for three of which he was indebted to Dr. Shine, Deputy Coroner.

The first was a heart, taken from a colored woman, forty-five years of age, who, after suffering for two years, subsequent to an attack of rheumatism with pain around the heart, suddenly dropped dead. On making the post-mortem examination, the principal lesion found was an extensive atheroma of the aorta, commencing at the semilunar valves and extending upwards. The ascending aorta was three times its natural thickness, and was much worm-eaten in appearance—at several points the external coat only remaining. The pericardium contained twelve ounces of serous fluid. Death was attributed to disease of the heart. The head had been examined and no lesion of the brain discovered.

Dr. Flint could not understand why death should have occurred as the result of the lesions found.

Dr. Finnell remarked that it was not an unusual circumstance to meet with just such cases, in which, in the absence of any better cause for death, insignificant

lesions of the heart were compelled to offer the explanation. Dr. Wooster Beach, who had given considerable attention to the subject, was of the opinion in common with himself, that there were in the present state of pathological science many unexplained causes for sudden death.

RUPTURE OF ANEURISM IN PERICARDIUM.

A second specimen, by DR. FINNELL, was an aneurism of the aorta, removed from a man aged 26. He had been very intemperate in his habits, and eight years ago suffered from rheumatism. He died suddenly, and on autopsical examination a small aneurismal pouch was discovered which had ruptured itself into the pericardium.

DEATH FROM HEART CLOT.

A third specimen was a uterus, containing a small polypoid growth, from the body of an intemperate woman, fifty years of age. She had drunk in the evening a pint of whiskey, and was found dead the following morning. On post-mortem examination, a large clot of blood was found in the left ventricle of the heart, to which was attributed the immediate cause of death. From the same individual were taken six hundred small gall-stones.

EXTENSIVE GUNSHOT WOUND.

DR. FINNELL presented, lastly, a class of specimens consisting of both lungs, heart, tongue, and a portion of the lower jaw, removed from the body of a woman who was shot by her husband. The first shot, which must have caused almost instant death, passed through the left arm into the left lung, across the aorta, through the right auricle and right lung, and finally lodged in the integument of the right chest. The second shot struck the lower jaw near the symphysis, splintering it; thence through the root of the tongue, lodging in the mastoid process of the opposite temporal bone.

ABSCESS OF OVARIES—PERFORATION OF RECTUM AND PERITONITIS.

DR. FLINT exhibited the uterus and ovaries taken from the body of a woman, aged twenty, who died within an hour after admission into Bellevue Hospital. Under the circumstances, the details of her previous history were very imperfectly obtained. It was ascertained, however, that three weeks before she had been seized with vomiting and diarrhœa, both of which were quite persistent, and that she had kept about until within a week of her admission. On examination, the abdomen was found very tense, but not tender on pressure.

At the autopsy there were evidences of extensive peritonitis in the shape of agglutination of the intestines, etc. The left ovary contained a multilocular cyst of considerable size, which had a free opening into the peritoneal cavity. The right ovary was also much enlarged, likewise contained a cyst which had two openings, one into the abdominal cavity, and the other into the rectum. Dr. Flint supposed the cavities in these ovaries to be the result of abscesses, and he did not think it likely that both would otherwise be perforated, but more especially that one of these communications should be with the rectum.

DR. JACOBI was of the opinion that the cervix uteri presented all the evidences of recent child-birth.

Dr. FLINT remarked that she denied the occurrence of any miscarriage or induced abortion.

DR. JACOBI thought that the process in and around the ovaries was inflammatory in character, as proven by the difference in the length of the Fallopian tubes, the condition of the cervix, and the deposit on the posterior part of the uterus, and the thickening of the right ovary.

DR. FLINT asked if the discharge of an ordinary ovarian cyst would be likely to produce peritonitis.

DR. JANEWAY remarked that this was one of the methods of cure laid down by Spencer Wells.

DR. ROGERS referred to a number of cases of rupture of ovarian cysts causing death, reported some years since by Dr. Lidell in the *American Journal of Medical Sciences*.

DR. CHAMBERLAIN did not see anything in either the uterus or ovaries indicating very recent inflammation.

DR. JACOBI was inclined to concur in this opinion, and did not think it impossible for an abscess in the ovary to remain for a considerable time unruptured.

RELAPSING FEVER.

DR. FLINT also exhibited some part of the body of the patient supposed to have had relapsing fever. He had been invited to attend an autopsy by Dr. Harris, but not having received the invitation in time, he only arrived at the Hospital just as the examination had been concluded. He remarked that it was a matter of regret that the stomach, which contained some interesting appearances, had been replaced in the body. The parts preserved were the large intestine, kidneys, liver, and lungs. The latter were studded with dark points, whether due to extravasations or not could not in the hurry of the examination be determined. He was sorry that he was not able to present more details, particularly as bearing upon the diagnosis. He had only a few moments' conversation with Dr. Harris, who stated that the patient apparently had relapsing fever, that he had what were supposed to be the primary paroxysms after a copious perspiration, was convalescent on the seventh day, and able to sit up and read the newspaper; then there were hemorrhages from different outlets, particularly from the stomach. Coincident with the phenomenon were dark spots under the skin, petechiæ. The stomach, as Dr. F. was told, contained a certain quantity of blood, with an abundance of extravasation. The large intestine, which was exhibited, showed a considerable quantity of blood on the surface of its mucous membrane, underneath which blood was also extravasated. As far as the intestines were concerned, the hemorrhage seemed to be limited to the colon. Both kidneys were enlarged, and the pelvis of one was filled with a clot of blood.

He stated that the specimen was not presented to illustrate the hemorrhagic character of relapsing fever, but the fatal tendency of a discharge of blood from the stomach.

In conclusion, he remarked that the story was that the whole family, of which the patient was the head, had taken the fever, and all, five in number, had died. This remarkable mortality, in the absence of the necessary details, threw a cloud of doubt upon the diagnosis. This family had been suddenly reduced from opulence to poverty, a transition which favored the ingress of any of the low-bred fevers.

THE CAUSE OF SUDDEN DEATH DURING CONVALESCENCE FROM PNEUMONIA.

DR. LOOMIS exhibited a specimen taken from a Swedish sailor, aged 28, who had been admitted into Bellevue Hospital on the second day of February. Three days before his entrance he was seized with a sharp chill, followed by constriction about the chest, some difficulty of breathing, some pain in the side, with cough, slight expectoration, and fever. These symptoms grew worse up to the time of his admission, and when received there his temperature was 103½°, and

his pulse 100. He gave the characteristic sputum of pneumonia, and physical examination detected its existence at the apex of the right lung. On the two following days his temperature was up to 104°, and pulse a little over 100. On the third day his temperature fell to 99°, and his pulse was about 80. His expectoration changed, his dyspnœa was relieved, his respirations decreased in frequency, and he was fairly convalescent. He had not been regarded as severely ill at any time. His convalescence was rapid and satisfactory, and he was soon up and around the ward. On the fourth of February, twelve days after admission, he suddenly died. About an hour before his death he was seen by the House Physician, and to all appearances he was as well as he had been some days previous. The urgent symptoms came on fifteen minutes before death, and before the House Physician could reach him he was pulseless. It seemed as though he was paralyzed on the right side. His countenance was not flushed, but his face was pale and his respiration gasping. No heart disease had been detected during his stay in the hospital.

The autopsy was made twenty-four hours after death. In one of the branches of the middle cerebral arteries was found a plug. The other portions of the brain were healthy. In each of the coronary arteries of the heart was a firm plug, one of which seemed to be continuous with a thrombus lying just above the aortic valves, the size of a hickory nut. The lungs were congested and œdematous, the right firmly bound down with pleuritic adhesions. The liver and spleen, as well as kidneys, were healthy, except one of the latter, imbedded in the substance of which were small yellow deposits.

Here, then, was a sudden death during convalescence from pneumonia, and the question was as to the cause. The occurrence was not very infrequent. Dr. L. believed that in these cases an œdematous and congested condition of the lungs was found, almost without exception, confined to parts not previously involved in the inflammatory process. Besides this condition the heart was impeded in its action by the presence of thrombi, giving rise probably to an almost complete obstruction at the aortic orifice. He believed that Dr. Flint regarded heart clots as not unfrequently a cause of sudden death in pneumonia. The left ventricle of the heart was not distended, and contained only a little fluid blood, but no clots. The patient had not been much reduced.

Dr. Flint thought that the problem of discovering the causes of death in such cases was very often a difficult one. Had not the sudden plugging of the arteries in this case something to do with it? Then again, might not the thrombi cause enough of obstruction to allow of sufficient accumulation of blood in the ventricle to create paralysis from over-distention? He believed that sometimes heart clots formed in the right ventricle, and were very often the cause of speedy death.

Dr. Janeway related the case of a patient at the almshouse who, last week, while convalescing from pneumonia, walked without permission a distance of a hundred yards towards the Penitentiary, and suddenly dropped down dead. On post-mortem examination the lower lobe of the left lung was found the seat of gray hepatization, and the rest of the lungs œdematous. The right heart contained a considerable-sized black clot. It seemed that in this case the œdematous and congested portions of the sound lung accounted for death. The brain had been examined and found healthy.

In answer to a question as to his patient, Dr. Loomis replied that the heart had been examined during life and no disease discovered.

Dr. Jacobi asked if death could not be explained in a different way, especially in such cases as the one related by Dr. Janeway. At all events the patient had been very much reduced, had gray hepatization and a good deal of collateral œdema in the lungs, and in all probability it had been a great effort for him to walk as far as he did. He thought we had a right to assume that the patient died in syncope. He remembered to have lost a case in just that way. A patient, fifty years old, with bilateral pneumonia, was improving, but was forbidden to get up. One day, instead of waiting for his nurse, this man walked to an adjoining room, had a passage from his bowels, and before he could get to his bed again, dropped dead. He remembered distinctly also two cases which were of children, during an attack of pneumonia, that fainted and died on being imprudently lifted out of bed. The cause for death in such cases seemed to be a sudden anæmia of the brain.

Dr. Loomis, in view of the possibility of sudden death, was always particular in keeping the patients in bed until convalescence was completed. Especially was this the case when there were evidences of œdema of the opposite lung.

Dr. Flint had no doubt that the rule was a good one, but as each rule had its exception, he would mention a case in point: While attending the Charity Hospital, N. O., he had a patient with pneumonia, who in a fit of delirium escaped from the institution without any clothing save his night-shirt, and walked a distance of two miles to his place of residence. He was brought back the next morning in a state of sanity, and from that time made a rapid recovery.

PERFORATING ULCER OF STOMACH.

Dr. Janeway exhibited, on behalf of Dr. Cushman, a perforating ulcer of the stomach, taken from a servant girl twenty-two years of age, who had been complaining for about a year with symptoms of dyspepsia, attended with vomiting and a localized pain a little to the left of the epigastrium coming on after eating. She was able to work until the day of her death, when, shortly after eating her dinner, she was seized with the symptoms of peritonitis, and died the following day at four o'clock.

The autopsy disclosed general peritonitis, caused by the escape of the contents of the stomach into the peritoneum. On the anterior surface of the organ, a little nearer the œsophageal than the pyloric orifice, and equidistant between the greater and lesser curvature, was found a round ulcer, an inch in diameter, smooth for the most part, except at its pyloric border, and adherent to the abdominal wall. The mucous membrane around the ulcer was slightly thickened. On the posterior surface of the organ, and almost opposite the perforation, a puckering of the peritoneal coat marked the site of a former ulceration that had healed. The former ulceration had been adherent some little time, and it was the giving way of the adhesion rather than the direct perforation that caused death. The patient had never at any time vomited blood.

LATENT BRONCHO-PNEUMONIA.

Dr. Lewis Smith exhibited the lungs and heart taken from an infant who died at the age of four months. When two months and a half old he had a severe attack of broncho-pneumonia, with all the usual symptoms, and after ten days appeared to be convalescent. A slight cough and acceleration of the respiration continued, however, eight or ten days after the commence-

ment of the improvement; the temperature was ninety-eight and a fraction, and the pulse was 124. Not much attention was given to the infant, as it was supposed to be out of danger, until the 21st of February, when it was observed to be sinking. It died very soon after, without any other diagnosis than that of bronchopneumonia being made.

On making the post-mortem examination, a moderate amount of colitis was found. The entire lower lobe of the right lung, with the exception of a very small point on the anterior margin, was in the second stage of pneumonia, as also the posterior half of the upper lobe and the posterior third of the lower lobe of the left lung. The point of interest was the latency of the pneumonia, the disease during all the time not progressing beyond the stage of red hepatization. Dr. Smith believed that in infants of that age the duration of the second stage was much longer than ordinarily supposed. The question also came up, whether it was a catarrhal or croupous form of the disease. He was inclined, from the granular and fatty character of the cells, to believe that it was of the former variety.

Dr. Jacobi concurred in that opinion, but did not see how it was possible, with the condition of cellular elements described, it could remain for so long a time latent. He could not alter such a view unless Dr. Smith had examined the patient within a week or so of his death.

DEATH FROM FATTY HEART.

Dr. Jacobi presented a heart removed by Dr. Wooster Beach, jr., from the body of a carpenter, forty-five years of age, who, while sawing a board, felt something give way about his heart, was faint immediately after, and before a physician could arrive, was dead. At the autopsy the valves were found healthy. The aorta was very much thickened, its lining membrane being covered at some points with yellowish-white prominences, and in other places with little indentations, evidently the result of a previous endo-arteritis. Directly over the semilunar valves, in the neighborhood of the pulmonary artery, was an aneurismal sac, hard to the feel, of a reddish color, similar to that of the heart substance itself. Right over the semilunar valves was a slit which communicated with this sac. It appeared that the aneurism was of the unusual variety known as the cystic saccated. Inside of it was a small layer of fibrine, which was discolored, showing that it had been deposited slowly and gradually. In all probability the cause of death was not in the aneurism, but in an intensely fatty heart, which at the particular time referred to became paralyzed from over-exertion.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Stated Meeting, Feb. 21, 1870.

Dr. George T. Elliot, President, in the Chair.

PATHOLOGY OF ECZEMA.

Dr. Foster Swift read an elaborate paper upon this subject, for which we must refer our readers to the *Journal of Dermatology* for April.

Dr. Boeck had often found benefit from the administration of iron in the first stage of eczema, the affection being frequently attended by anæmia. In the latter stages of obstinate general eczema, he had found a perfectly dry treatment of great value, avoiding baths, which were apt to aggravate the trouble. Of all the ointments, he preferred those made from pitch, of which the less irritant kinds should be selected. General eczema was often accompanied by visceral diseases, for which he always made careful examination. He had found renal disorders in this connection, and the post-mortem had sometimes revealed cancer of the uterus, unsuspected by the patient during life.

Dr. W. H. Draper had found the paper so exhaustive upon the pathological anatomy of the disease, that the only topics left open for discussion were the ætiology and the treatment. As to the first, it seemed to him that we were too much inclined, at the present day, to look upon eczema as a purely local affection, requiring only local treatment. He had been much struck with Dr. Boeck's remark about its frequent association with internal disorders. He thought we often also found it associated with diathetic disorders—for example, the gouty or rheumatic. Its connection with gout, both in acute and in chronic cases, he had very often observed. In this affection we had, of course, acting through the capillary circulation of the skin, the same materies morbi which we found acting through that of other organs, and producing irritations that manifested themselves by skin-affections well recognized. This view of the ætiology was supported by the marked success which would sometimes follow its recognition, as a guide to the treatment of cases of eczema which obstinately refused to yield to local treatment alone. As soon as we began an anti-arthritic regimen, whether medicinal or hygienic, the skin-affection would begin to improve.

Dr. Haight thought that the subject of the diathetic origin of skin diseases was still very much in the dark, and that little light had been shed upon it by the French apostles of the doctrine. Observations on a large scale showed the percentage of patients suffering from both gout and eczema to be quite small; and out of three hundred cases of well marked eczema in the Hospital of Vienna, less than seventy showed any taint of scrofula.

The plan of treatment introduced by Hardy, and employed more extensively by Hebra—that of covering the surface with india-rubber—had been attended with excellent results, and Hebra regarded it as at least an invaluable adjuvant. It had the advantage of such simplicity that it could be left in the hands of the patient himself, requiring only cleanliness. It was, moreover, applicable to all stages of the affection, and therein possessed a marked superiority over the complicated treatment of the German school. For example, the tarry applications, so highly commended, he had heard much abused in England, the reason being that they were used at the wrong stage. For tar might be as harmful as helpful in eczema, unless rightly employed.

Of the "impetigo contagiosa," of Dr. Tilbury Fox, he had seen several examples. It was not to be regarded as true eczema, though it began with a vesicle, almost a bulla, surrounded with scarcely any areola. It was certainly contagious, and it was very amenable to treatment.

Dr. R. W. Taylor had, under Dr. Draper's direction, examined many cases of eczema with a view to their ætiology. He had found abundant in the urine the products of incomplete oxidation, uric acid, the urates, oxalate of lime, etc.; and when oxidizing agents, such as chlorate of potassa and nitric acid, were given, their effect on the skin-disease was remarkable. A dispensary patient with severe eczema, and also gouty symptoms, showed uric acid both in the urine and in the blood. If these cases were carefully examined with reference to their antecedents, as well as to their present condition, they would no doubt afford much support to the diathetic doctrine in the modified form held by Dr. Draper, though perhaps not to the extreme views of Bazin and his followers.

Dr. Piffard had at first been unprepared to give any credence to Bazin's theory of the arthritic diathesis; but he had since made careful inquiries of his patients, and found a history of gout or rheumatism in a large proportion of cases, while, in some, concomitant cardiac affections gave further proof of the diathesis. But it was very difficult to decide, from the obscure statements of a patient about his pains, etc., whether or not he had suffered from a gouty or rheumatic tendency. Similarly the connection of eczema with scrofula was apt to be obscured; for commonly there was no marked evidence of scrofula, except in the sluggishness of the eruption and of the circulation. In children the immediate cause was generally found to be some disorder of the digestive organs, whether or not this accounted for the tendency to the disease. In those at the breast, the first signs of extensive eczema were often clearly traceable to a change of diet; and if suitable breast-milk could be procured, the eruption would very likely disappear of itself. If good milk could not be obtained, cod-liver oil was better for these infants than arsenic or other medicines.

As to the pathological anatomy, the day of the vesicle was evidently past. Milton now claimed that vesicles never occur in eczema, basing his assertion upon the examination of many thousands of cases, in which he had failed to discover one. The speaker had inquired of many dermatologists upon this point, and had not found any who had ever seen an eczematous vesicle. You would often get pseudo-vesicles. From the application of caustic potassa you might get little droplets of serum upon the surface; but touch them with a needle, and the fluid would cling to the needle with no rupture of the epidermis. He had watched these cases with a magnifying glass from hour to hour, and had found but one instance of true vesicles accompanying eczema—except in cases of itch, where you might have eczema as a concomitant, and where the vesicles probably belonged to the itch.

Dr. Henry had, in several instances, observed gout and eczema in the same persons. He had also, and especially among the poorer classes, found the strumous diathesis much more frequently associated with eczema than would appear from the tables quoted by Dr. Haight. He wished to give Dr. Swift the credit of having first brought the india-rubber treatment to the notice of the profession in this country.

Dr. Draper would not be understood as advocating the diathetic pathology in a partisan way; but he thought it important to recognize the principle, and in two of the diatheses at least—the gouty and the syphilitic—we could hardly fail to do so. The scrofulous diathesis had been mentioned as not discoverable in a large number of cases of eczema examined by Hebra. Probably no one could at present tell exactly what was meant by the scrofulous diathesis, although all recognized it in an indefinite way, as demanding a certain treatment. With syphilis the case was different. Here we had a poison which, though not yet isolated, we knew to be specific, and which certainly produced some wonderful affections of the skin. So with regard to gout—we knew it was due to urate of soda, and this we could find deposited in and about the joints. Although the pathological anatomy of eczema had, as he before remarked, been exhausted by Dr. Swift, yet we might seek to go a step behind the microscope. The affection was unquestionably a dermatitis, but what produces the dermatitis was the question that concerned us as practitioners. We all recognized certain local causes, and knew the importance of striving to find these in each individual case; but failing in this, we must search for the constitutional cause.

The President spoke of a lady patient who had long been wont to cure eczema on her fingers by wearing an india-rubber glove.

Upon motion of Dr. Hammond, a committee of three was appointed to inquire into the merits of a statue of Harvey, by Dr. Horatio Stone, and report upon the expediency of recommending that a bronze copy of the same be placed in Central Park. The President appointed Drs. Hammond, James R. Wood, and Bibbins.

The Society adjourned.

Correspondence.

GLYCERINE ADHESIVE PLASTER.

To the Editor of the Medical Record.

Sir—The manufacturer of "Tallman's Glycerine Adhesive Plaster" has had the impudence to send me a roll of his plaster, with a circular containing his advertisement. The reference to myself as having recommended his plaster in my Treatise on Military Surgery contains a falsehood which I am not willing should pass unnoticed. In the circular I am quoted as saying:

"As an adhesive plaster the surgeon will need on the field Tallman's Glycerine Adhesive Plaster, which does not require the aid of heat in its application, but only needs to be moistened slightly upon one surface."—*Treatise on Military Surgery, by Frank Hastings Hamilton, M.D.*

What I said was: "As an adhesive plaster the surgeon will need, when on the field, either Tallman's or Husband's isinglass plaster, neither of which require the aid of heat."

This was in my first edition. In my second I spoke only of isinglass plaster, mentioning the names of no manufacturers. The truth was I found Husband's the best; but I believe there are many other manufacturers who make equally good plaster.

I wish my professional brethren would rebuke this rascally practice of using our names falsely, or without authority, by refusing to purchase the articles they advertise.

Incidentally I may say that the assumption that it is any more "soothing" because it contains glycerine is simply absurd.

The man Tallman, who has thus shamefully misquoted my language, lives at Janesville, Wis.

Very truly yours,
FRANK H. HAMILTON.

Extraction of a Needle.—A child (*Chicago Medical Examiner*) was suddenly seized with violent coughs, choking and dyspnœa, which lasted several hours, after which she breathed naturally. In about six months she complained that something hurt her back. On examination, what seemed a small pin was discovered just below the inferior angle of the right scapula, pointing externally. It disappeared and reappeared several times. A few months after, it was decided to remove the substance, when, on cutting down upon it, the pointed end of a needle about eight lines in length was extracted. There was no suppuration before or after the operation.

Placenta Prævia.—This complication is variously estimated by different authorities to occur from 1 in 500 to 1 in 1,000 cases. The average statistics, from various sources, give as the result, 1 in 3 of the mothers, and over one-half of the children lost.—*Trans. Ill. Med. Society.*

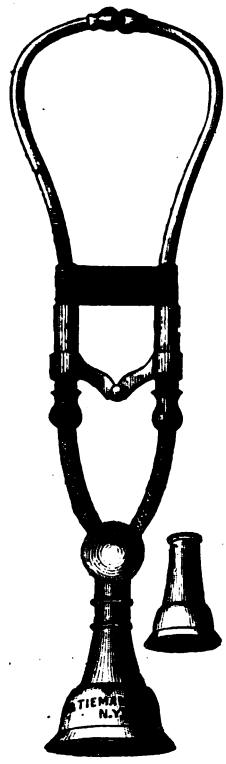
New Instruments.

IMPROVEMENT OF CAMMANN'S STETHOSCOPE.

By THOMAS G. SNELLING, M.D.,

NEW YORK.

For the past four years I have been in the habit of employing a modification of my own of Cammann's stethoscope, which, in cases where much accuracy is required, as in an examination in consultation of heart or lungs, or where it is desired to precisely locate a morbid sound, or in chests which are much emaciated, I have found to be a very great advantage. It can also be used indifferently upon Cammann's stethoscope or upon the ordinary flexible tube instrument.



It consists simply of an india-rubber rim attached to, and acting as a continuation of the rim or lip of the ordinary mouth of the stethoscope, by which, even by the most gentle pressure, all air is excluded by the elastic expansion of the india-rubber rim.

Its advantage will be evident at a glance in auscultation over the carotids, where the pressure made by the ordinary unshielded lip of the instrument must cause an adventitious murmur; over the jugulars for venous murmur, over or under the clavicle when a patient is so thin as to preclude the complete adjustment of the ordinary instrument to the exclusion of the air; in patients so emaciated as to make it impossible to apply the sounding tube upon or between the ribs, and where it is desirable to locate a cardiac murmur over one or another valve.

Prof. Flint informs me that he regards it as a real and valuable improvement, and recommends it to the use of his class. Its advantages will be abundantly evident on trial. The following is a representation of it applied to the larger tube of Cammann's stethoscope. The instrument is made by Tiemann & Co. of New York.

72 Madison Av., N. Y.

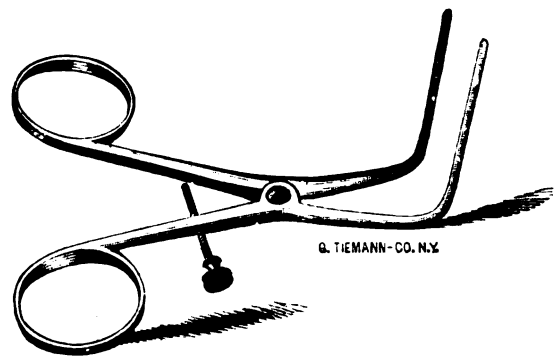
ON THE TREATMENT OF ACCIDENTAL PHIMOSIS BY RUPTURING THE MUCOUS MEMBRANE OF THE PREPUCE.

By J. C. HUTCHISON, M.D.,

SURGEON TO THE BROOKLYN CITY HOSPITAL, PRESIDENT OF THE NEW YORK PATHOLOGICAL SOCIETY, ETC.

Some years ago a child was brought to my surgical clinique to be treated for congenital phimosis. On retracting the foreskin to ascertain the size of the preputial opening, it occurred to me that by applying considerable force with the thumb and fore-finger, the mucous layer, which is the seat of the constriction, might be ruptured, and the skin retracted behind the corona glandis. This was accordingly done, and the mother was directed to retract the prepuce behind the corona several times a day until the rent had healed. The child was not presented again, and what the ultimate result was I am unable to say. This operation is not presented as a proper one for *congenital* phimosis. Such cases should be circumcised. But it suggested that in cases of *accidental* phimosis, the result of thickening or contraction of the prepuce after balanitis or the cicatrization of a chancroid, dilatation might be easily and safely effected by means of the forceps described below. The operation is analogous to that proposed by Mr. Barnard Holt for the treatment of stricture of the urethra by splitting the stricture.

The instrument by which this simple process is accomplished consists of a pair of forceps, of which the upper part of the blades, an inch and an eighth in length and one-eighth of an inch wide when closed, is set at a right angle to the lower part, the outer edges and points being well rounded and smooth, so as not to injure the mucous membrane. There is also a screw which regulates the distance to which the blades may be expanded. When fully opened they are separated an inch and three-quarters (*see illustration*). I have



heretofore in my operations expanded the blades to their full extent, but this may not be necessary in all cases.

The operation consists in introducing the blades of the forceps closed through the preputial opening and along the dorsum of the glans penis as far as the corona. They are then suddenly expanded, and withdrawn fully dilated. The prepuce can at once be retracted behind the corona glandis, when it will be found that the mucous membrane has been split at the seat of stricture, the skin being uninjured unless the phimosis has been produced by a cicatrix at the preputial orifice, which existed in one of my cases, and was ruptured. The patient is now directed to retract the prepuce behind the glans several times a day, especially during micturition, both in order to prevent the contact of the urine with the wound, and also the too rapid union of the ruptured edges, which would reproduce the disease. The patient should be cautioned not to leave the foreskin retracted behind the glans, for swelling might occur to such a degree as to cause paraphimosis. This indeed happened in one case at the Brooklyn City Hospital which was operated upon by House Surgeon H. T. Pierce. The prepuce was drawn forward by the usual manipulations, aided by ether spray thrown upon the glans by Richardson's atomizer, to diminish the size of the organ. This operation should not be practised when chancroids are present, for fear of inoculation, nor until sufficient time has elapsed for the phimosis to disappear spontaneously.

The above operation has now been repeated nine times by myself and House Surgeon H. T. Pierce with the most satisfactory results. It will be found, I think, to possess the following advantages over the methods of treatment ordinarily practised:

1st. It is preferable to circumcision, or slitting up the prepuce, because it is simpler, is done more quickly, and there is no hemorrhage requiring the use of hemostatic agents. But when the prepuce is much diseased circumcision should be preferred.

2d. It is better than simple dilatation by means of Thompson's urethral dilator, as suggested by Mr. Erichsen, because the contraction is less likely to recur after rupture than after dilatation.

3d. It is preferable to simple division of the mucous layer of the prepuce, which is done by thrusting one blade of a sharp pair of scissors between the layers of the prepuce while the other is carried along the dorsum of the glans penis so as to divide the mucous membrane to the corona glandis, because there is less danger of a reproduction of the disease after a rupture than after an incised wound.

This last operation was first proposed by my friend, Dr. Edward Peace, lately Surgeon to the Pennsylvania Hospital, and I am informed that it is still practised in that institution.*

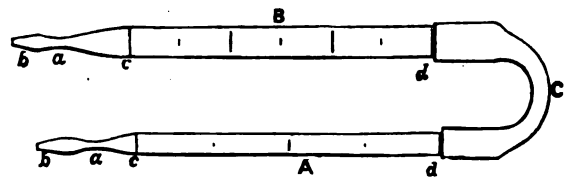
A NEW HYPODERMIC SYRINGE.

By J. H. BILL, M.D.,

SURGEON, U. S. ARMY.

An improvement in the hypodermic syringe in ordinary use may at first seem to many a work of supererogation. The writer, thinking it an important matter in practical medicine, begs leave to present his views.

The hypodermic injection of remedies, especially of the neurotics, has of late years been almost universally adopted by the profession; for besides the convenience of application and the promptness with which it may be brought to bear, there is the fact that by its use we become quite independent of gastric irritability. Moreover, the hypnotics at least seem to possess more power, and especially more of that kind of power which we wish in an hypnotic, with less of the injurious unsought-for effects when given hypodermically than when swallowed. The method is undoubtedly still gaining favor, and receiving new applications. And yet what discrepancies as to effects, doses, etc., exist!—one habitually using the twentieth of a grain of atropia, another finding the fortieth dangerous; some arguing that remedies will act in smaller doses, others that larger doses are required, hypodermically. The writer believes that one reason for this lies in certain imperfections of the instrument. Another reason is the indefinite way in which writers have recorded their experience of its use and effects. As to the instrument, the writer is sure that he owed most of his doubts and fears to its imperfection. The first syringe he used was made of glass, with silver caps on top and bottom, the piston-rod being of silver, and having worked on it a screw provided with a nut by which was regulated the quantity of liquid to be injected. In a case of traumatic delirium, in which a quarter, then a half, and finally three-quarters of a grain of morphia (of course at suitable intervals), were given, at first without effect, afterwards, after the last dose, profound coma came on from which the patient was aroused with some difficulty, the writer was greatly perplexed, for if the cause for such inequality of action could not be discovered and prevented, the method itself was unsafe. Frequently, too, it would happen that one-fourth of a grain of morphia would produce no effect; usually, however, this quantity was all that was required. The solutions were examined, and, being found full of cryptogams, new ones were employed; but still the erratic power of the method was experienced. To be sure this did not last long, for, using the syringe one day, in broad daylight, it was discovered that although some of the liquid went under the skin, most of it ran over the skin, for the syringe leaked at the junction of the glass and lower silver cap. Melting the cement merely temporized; the instrument presently leaked as badly as ever. Moreover, one end of the glass cylinder being a little larger than the other, the piston would at first move with difficulty, and on applying more force, as the larger end of the cylinder was reached, the piston would fly up with a jerk. It was evident that with this instrument there would always be uncertainty, and although beautifully made, by one of the best cutlers in Philadelphia, it was laid aside. A gutta-percha syringe, from the shop of a celebrated New York cutler, was next used. It worked very well for a while, but on one occasion, failing entirely to get the expected effect from a full dose of morphia, it was discovered that instead of injecting the liquid into the patient's cellular tissue the piston had gone through the liquid in the cylinder, allowing this to occupy the upper part of the latter. After arranging the packing of the piston, on introducing this into the cylinder the piston-rod broke off short close to the piston. This compelled the writer to construct a new instrument. So much has been written as apology for writing at all about hypodermic injections. His device for effecting hypodermic injections, at first the result of necessity, has now become with the writer a matter of choice. The advantages claimed



are: 1st, Strength, efficiency, and absence of leaks. 2d, Cheapness and simplicity; it can be made by any one. 3d. Graduation into minims and not into indefinite quantities. The instrument employed is represented half size. Two heavy fusible glass-tubes are connected by rubber tubing, the smaller tube having a calibre of $\frac{3}{16}$, the larger of $\frac{1}{4}$ in. or a little less. The ends of both tubes are drawn out in the flame of an alcohol lamp into necks *a*, which, however, gradually swell into shoulders of a diameter somewhat less than that of the tube, which shoulders again taper off conically into points *b*. To graduate these tubes, drop a little water into them, sufficient to reach about to *c*, at which place a slight scratch with a flint or *round* file should be made; counterpoise on a rather delicate scales, then fill up the tube with water at 62° F. until A weighs 19 grains and B weighs 28·5 grains (the former will have received twenty, the latter thirty minims of water). Place the tubes upright, and mark with a second scratch, *d*, the height of the liquid. Then divide A between *c* and *d* into four parts, and B between *c* and *d* into six parts. Roughen the points of

* Since the above was written, *Braithwaite's Retrospect* for Jan., 1870, has come to hand, and I find that it contains an account (from the *Dublin Quarterly Journal*, Nov. 1869) of an operation identical with the one described above, with a similar instrument, by Dr. F. B. Cruise, of Dublin. My first operation with an instrument was done on a medical friend, August 1st, 1869. My instrument was shown by Dr. Stein at the New York Medical Journal Association, Dec. 3d, 1869. (See MEDICAL RECORD, Jan. 1st, p. 503.)

both tubes with a flat file, and, finally, file away the closed extremity until an orifice is obtained the size of a pin. Connect the two tubes by the rubber c, and the apparatus is ready for use. The ordinary hypodermic points without screws may be employed, although a fine exploring canula is better, for with the latter it is always possible to avoid wounding a vein. Thus: Pass the triangular point of the trocar through the skin pinched up, engage the tips of the canula in the orifice so made, withdraw the trocar, and pass the canula on into the cellular tissue. If using a solution of morphia or strychnia, dip the end of the smaller tube into this, and, holding the smaller end of the larger tube between the lips, apply suction until the liquid rises in the small tube to *d* or perhaps a little above this. Apply the tip of the tongue to the end of the tube held by the lips, and carry the whole instrument in this way to the patient. Insert the end *b* of A into the mouth of the hypodermic point, applying the two firmly against one another, and then gently blow the liquid in A through the hypodermic point into the cellular tissue until the line at *c* is reached. The point is then removed. Thus no air can be blown into the tissue, for there is always the liquid from *c* to *b* left in the tube, whilst the operator can be sure that twenty minims have been injected under the skin. The operation requires the exercise of considerable force by the buccal muscles. A small bit of fine rubber tubing fastened to the mouth of the hypodermic point and clasping tightly the shoulder and neck of the glass tube, when this is thrust into the open mouth of the hypodermic point, is an improvement. The large tube B is intended for injections of quinia, fluid extracts, etc. Particular attention is called to the fact that by this apparatus we inject a certain number of *minims* of liquid; thus it is easy to obtain from any apothecary, by an ordinary prescription, the liquids of the strength required.

The writer has found the following formulæ the most convenient:

Atropized Morphia.

Take of Sulphate of morphia, grs. xij.
Sulphate of atropia, gr. ½.
Water, f ℥ iss.
Dose, M xv. = ¼ gr. morphia, $\frac{1}{96}$ gr. atropia.

Atropia.

Take of Sulphate of atropia, gr. j.
Water, f ℥ ij.
Dose, M xv. = $\frac{1}{64}$ gr. atropia.

Morphia.

Take of Sulphate of morphia, gr. xij.
Water, f ℥ iss.
Dose, M xv. = ¼ gr. morphia.

Quinia.

Take of Quinia, grs. 200.
Ether, a sufficiency.
Dissolve the quinia in the ether and evaporate to 600 M.

The writer uses a hypodermic case, which he finds very convenient. A block of fine-grained wood is selected. This is six inches long, one inch thick, and two and a half inches high. By a fine saw this is split down the middle in the direction of its length. In the bottom piece so obtained, five holes are bored, not quite through the bottom of the lower piece. Into these fit accurately five stoppered bottles. The fifth bottle is filled with glycerine, and is fitted with a cork through which pass the hypodermic points into the glycerine; they are thus kept ready for use. The top piece is scooped out with gouge and chisel and room is thus made for the stoppers of the bottles, whilst ample space is left for the hypodermic pipette, as it may be called; hinges added at one end, and an india-rubber band towards the other, complete the arrangement.

This communication cannot better be closed than by calling attention to the expediency of recognizing in the U. S. Pharmacopœia for 1870 formulæ for hypodermic injections. The giving of morphia by the mouth ought to be discouraged, save as an exceptional thing. Morphia is a dangerous remedy, especially when exhibited (as it is by the majority of country practitioners) —*by the pinch*. Hypodermy makes accuracy easy as well as compulsory. When long-continued use of morphia is required, the danger of the habit of opium-eating will be avoided if we inject the opiate. These solutions are apt to be infested with cryptogams, to prevent which, boil the solutions when first made, and put them away carefully stopped, not corked. Phenol in reasonable quantity will not prevent the formation of these growths. The sulphates are the most eligible salts, but only because they can be got purest. Particularly unsuitable for hypodermic injection is the so-called unbleached morphia, *i.e.* morphia containing a variable quantity of dark, gummy, and resinous matters, which will make turbid solutions. There is one thing more. With the hypodermic pipette it is impossible to introduce a liquid save into the cellular tissue, unless one should be so careless as to open a superficial joint. If it is found impossible to make the liquid flow, it may be understood that a wrong spot has been selected. Thus it is not easy to make an injection over the platysma in some subjects, as this muscle has strong attachments to the skin. The outer edge of the deltoid will usually be found the most convenient spot; so also any spot situated over the ribs, when these are not covered with much muscle. The injection will begin to show its effects in fifteen minutes, and in half an hour it may be repeated, if it was at first without effect.

Fort Vancouver, W. T.
Jan. 30, 1870.

Medical Items and News.

Dr. Samuel Peters, of Crescent, Saratoga Co., N. Y., was the author of "Chlorate of Potassa in Serous Effusions," presented to the State Society, erroneously credited to "*Dr. J. C. Peters, of New York.*"

Breast Drawing.—In a late meeting of the *Boston Obstetrical Society*, Dr. Reynolds stated that, with most nipples, he thought the best way of drawing the breast was to use Thier's pump; called the "Téterelle Thier." —*Boston Med. and Surg. Jour.*

Imperial Honors to Dr. Ricord.—This distinguished Syphilographer has been made, like Nélaton, a Senator. The Emperor, during his late illness, gave M. Ricord a gold snuff-box ornamented with diamonds, worth 20,000 francs.

A New Application to Ulcerated Surfaces.—Dr. Richardson, of London (*Boston Med. and Surg. Journal*), advocates the solution of xyloidine and tannin in ether, as an application to ulcerated and raw surfaces. It acts as an antiseptic by reason of the tannin it contains.

Teratology.—To Stephen and I. G. St. Hilaire is given the credit of having founded this science, at the end of the first quarter of the present century.

A Large Number of Cases of Midwifery.—The late Dr. Hooker, East Cambridge, Mass., in forty years tended eight thousand cases of midwifery.

Death of Dr. George C. M. Roberts.—Dr. Roberts, Emeritus Professor of Obstetrics and Diseases of Women and Children in Washington University, Baltimore, M.D., died in January last.

The Fatality of Tetanus.—The fatality is least in tropical climates. In the West Indian war, 43 per cent. recovered; 7·4 was the percentage in the American war, and Prof. Busch, of Bonn, saved 33⅓ per cent. during the Bohemian war.

Prof. Liebig's Soup.—One ounce of ox-marrow, ½ gallon of water, a sufficient quantity of vegetables—carrots, celery, cabbage, etc.,—boil for one hour and a quarter, then add 5 drachms Liebig's *meat extract*, and salt q. s. This is sufficient for seven persons.

Pruritus Pudendi.—The treatment of this troublesome affection is sufficiently various. Dr. Elleaume, of France, uses injections of a watery solution of starch, and powders the vagina with starch, having one-eighth of its weight of nitrate of bismuth added to it. M. Hartman uses a decoction of white hellebore as an injection. Trousseau recommends a lotion of one part of carbonate of potassa in twelve of water, and where that fails, a weak spirituous lotion containing a little corrosive sublimate. Dr. Storer prefers an ointment containing hydrocyanic acid and acetate of lead; but he finds it necessary to adapt the treatment to each individual case. An ointment containing two grains of acetate of morphia and one drachm of glycerine to an ounce of cold cream or simple cerate will often give great relief.

A Substitute for the Platinum-Still.—M. Cotelle (*The Pharmacist*) has invented a cheap substitute for the platinum-still used in distillation of sulphuric acid. It consists of a stone tower, into which the acid drops in small quantities, while a current of hot air enters at the bottom and drives over the acid, which is condensed in the usual way.

The Increase and Decrease of Starch in Potatoes.—During the storing of potatoes in the cellar, up to January, the amount of starch is increased; towards spring it diminishes, on account of the change into glucose and dextrine.—*The Pharmacist.*

Napoleon's Disease.—Nélaton calls Napoleon's malady *vesical hemorrhoids.*

Herpes in Children.—Dr. Erasmus Wilson (*Jour. of Cutaneous Medicine*) states that herpes is not common in infancy, and he does not remember to have met with an example in an infant under twelve months old. Dr. L. Thomas, in the *Archiv der Heilkunde*, reports an instance of this disease in an infant only ten months old, the seat of the eruption being the right buttock, the thigh, leg, and foot. Von Barensprung regarded the affection as not uncommon in children, and mentions its occurrence between the ages of eighteen months and five years.

Lunatics, Idiots, and Cretins in France.—A splendid volume, issued from the Statistical Department of France, gives for 1866 the results of investigation into the psychological condition of the country. The lunatics number 50,726, or 133 for each 100,000 inhabitants. Of this number 63 per cent. are treated in asylums. The proportion of the sexes is 91 men to 100 women. In the department of the Seine, however, the ratio rises from 133 to 239, in Seine and Oise to 299.

Idiots and cretins count 39,953, or 105 per 100,000 inhabitants. The proportion of the sexes is inverse to that of lunatics, 132 men suffering from these forms of lunacy to 100 women. Almost the whole of this class remain with their families, not more than 1,500 being confined in asylums.

Chair of Dermatology in the Royal College of Surgeons of England.—The Council of Surgeons have conferred upon Dr. Erasmus Wilson, F.R.S, the appointment of Professor of Dermatology in the Royal College of Surgeons.

The Number of Druggists in Dublin. There are only 42 retail druggists in Dublin—one to each 7,000 inhabitants.

Alcohol from Iceland Moss.—A method has been discovered of producing alcohol from Iceland moss by M. Sternberg, of Stockholm. A company is being organized in Sweden for the manufacture of this spirit on a large scale.

Does Chloroform Influence the Rate of Mortality after Operations?—Simpson believes that mortality has lessened since the introduction of chloroform. According to the figures of J. Arnott, it has increased in amputations by 12, and in lithotomy by 28 per cent. Mr. Erichsen is inclined to think that the rate of mortality has increased since the use of chloroform in operative surgery. When the nervous power is enfeebled, or the blood in an unhealthy state, undoubtedly Mr. E. is right when he says, chloroform does exercise a noxious influence on the constitution and lessens the prospect of recovery.

A Case of Elephantiasis of the Leg Cured.—Dr. Arthur Mehern Norton (*Trans. of Clinical Soc. of London*) publishes a case of *Elephantiasis of the Leg*, of ten years' standing, cured in ten months by the application of a tight bandage.

Diminution of Weight in Man during the Cold Months.—Mr. Milner, of Wakefield (*Am. Jour. of Med. Sciences*), some years since performed a series of experiments with a view of determining the periodical fluctuations in weight, substance, and form, which the whole body undergoes. He weighed every prisoner upon his entrance into the convict establishment at Wakefield, and subsequently at the end of every calendar month, all of them being subjected to similar conditions of temperature, food, exercise, and ventilation. The number of men weighed exceeded 4,000, and the total number of individual weighings was 44,004. From his experiments it was found that there was a progressive loss of weight in January, February, and March, and a gain in April, May, June, July, and August, and a loss in September, October, November, and December; or, in other words, an increase of weight during the hot months, and a diminution during the cold. These results are in accordance with physiological truth, for Dr. G. Smith has shown that the quantity of carbonic acid exhaled in winter is largely in excess of that given out in summer, and the sudden weight in April is found to correspond with an equally abrupt diminution in the quantity of carbonic acid expired.

An Adaptation of the Reflecting Mirror to the Uterine Speculum.—Dr. Sedgwick, of London (*Am. Jour. of Med. Sciences*), recently exhibited to *St. Andrew's Med. Graduates Association* an adaption of the reflecting mirror to the uterine speculum. It consists simply in attaching to the vaginal speculum an ordinary reflecting laryngoscopic mirror, by means of an arm with a ball-and-socket joint. When the mirror is used, it is unnecessary to alter the position of the patient, for no matter what the source of light may be, the mirror can be adapted so as to reflect on the cervix

uteri, and a better illumination may thus be obtained either by day or candle-light, and the danger of spilling grease on the patient's clothes is obviated, while both hands of the operator are left free.

MATERNAL MORTALITY IN THE NIGHTINGALE LYING-IN WARD, KINGS COLLEGE HOSPITAL, LONDON.—This ward was set apart at the top of this Hospital, at the request of Florence Nightingale, for the instruction of young women in nursing and midwifery. Directly below the lying-in ward is a medical ward, and below that again a surgical ward, all communicating with the shaft around which the staircase wound. Since its opening, January, 1862, six years, the average maternal mortality has been 1 in 28.9 labors. In the lying-in hospitals of Paris, St. Petersburgh, London, Vienna, Glasgow, Liverpool, and Dublin, the statistics of 90,000 cases show an average mortality of 1 in 29.3 labors. At the Rotunda Hospital, Dublin, the average for six years, 1861 to 1866, was 1 in 34.9. In the British Lying-in Hospital, 1 in 54.8.

SIAMESE TWINS SURPASSED.—All the stories told of the Siamese Twins hardly equal this of the famous Scotch double man, of whom the following account is given in the *Regum Scotorum Historia:* During the reign of James the Third, of Scotland, and at his court, there lived a man double above the waist, single below that region. The King caused him to be carefully brought up. He rapidly acquired a knowledge of music. The two heads learned several languages; they debated together, and the two upper halves occasionally fought. They lived generally, however, in the greatest harmony. When the lower part of the body was tickled the two individuals felt it together; but when, on the other hand, one of the upper individuals was touched, he alone felt the effect. This monstrous being died at the age of twenty-eight years. One of the bodies died several days before the other.

THE MEDICAL INSTITUTIONS OF THE UNITED STATES.—Dr. Th. de Valcourt, of Paris, in his Report to the Minister of Public Instruction, on "The Medical Institutions of the United States," sees a good deal to condemn and much to praise, with reference to our medical schools, medical societies, and hospitals. The organizations of the Harvard and Bellevue Medical Colleges are admired, with a minute description of the airy, clean, and well-ventilated lecture-room and laboratory of the latter institution. The Bellevue Hospital is pronounced faultless; "its wards are very clean," and the Boston City Hospital is represented "as so beautiful and so full of every sort of innovation, that it seems expressly constructed for the purpose of making everybody despair who is smitten with a passion for improvement."

He gives a glowing account of the rich museums of Boston and Philadelphia, while the Army Museum at Washington is described as "beyond all doubt the most curious, the most instructive, and the most complete in the world."

VERY OLD LIVING PEOPLE.—*Hannah Finnimore*, of Delaware, was 108 years old, December 10 (only 29 years younger than Gen. Washington), was 14 years old when the battle of Lexington took place, and 21 years old at the close of the Revolution. She first lived in the kingdom of Holland, 8 years from the time of her birth, in 1761 to 1769; then in the British colonies under the reign of King George, a period of 7 years, until the Declaration of Independence, under which she has ever since resided.

John Kitts, 107 years of age, and a soldier of the Revolution under Lafayette, has applied to the Baltimore City Council for an appropriation.

AMERICAN MEDICAL ASSOCIATION.—The Twenty-first Annual Session will be held in Washington, D. C., May 3, 1870, at 11 A.M. The following committees are expected to report:—

On Cultivation of the Cinchona Tree—Dr. Lemuel J. Deal, Pennsylvania, chairman. On the Cryptogamic Origin of Disease, with Special Reference to Recent Microscopic Investigations on that Subject—Dr. Edward Curtis, U.S.A., chairman. On the Doctrine of Force, Physical and Vital—Dr. John Waters, Missouri, chairman. On Variola—Dr. Joseph Jones, Louisiana, chairman. On the Relative Advantages of Syme's and Pirogoff's Mode of Amputating at the Ankle—Dr. G. A. Otis, U.S.A., chairman. On a National Medical School—Dr. F. G. Smith, Pennsylvania, chairman. On Commissioners to Aid in Trials involving Scientific Testimony—Dr. John Ordronaux, N. Y., chairman.

On the Climatology and Epidemics of—Maine, Dr. J. C. Weston; New Hampshire, Dr. P. A. Stackpole; Vermont, Dr. Henry Janes; Massachusetts, Dr. H. I. Bowditch; Rhode Island, Dr. C. W. Parsons; Connecticut, Dr. E. K. Hunt; New York, Dr. W. F. Thoms; New Jersey, Dr. Ezra M. Hunt; Pennsylvania, Dr. D. F. Condie; Maryland, Dr. O. S. Mahon; Georgia, Dr. Juriah Harriss; Missouri, Dr. Geo. Engleman; Alabama, Dr. R. F. Michel; Texas, Dr. T. J. Heard; Illinois, Dr. R. C. Hamil; Indiana, Dr. J. F. Hibberd; District of Columbia, Dr. T. Antisell; Iowa, Dr. J. C. Hughes; Michigan, Dr. Abm. Sager; Ohio, Dr. T. L. Neal; California, Dr. F. W. Hatch; Tennessee, Dr. B. W. Avent; West Virginia, Dr. E. A. Hildreth; Minnesota, Dr. Samuel Willey; Virginia, Dr. W. O. Owen; Delaware, Dr. L. B. Bush; Arkansas, Dr. G. W. Lawrence; Mississippi, Dr. W. Compton; Louisiana, Dr. D. L. Pimm; Wisconsin, Dr. J. K. Bartlett; Kentucky, Dr. J. D. Jackson.

On Veterinary Colleges—Dr. Thomas Antisell, D. C., chairman. On Medical Ethics—Dr. Lewis A. Sayre, N. Y., chairman. On American Medical Necrology—Dr. C. C. Cox, Maryland, chairman. To Memorialize State Medical Societies—Dr. N. S. Davis, Illinois, chairman. On Nomenclature of Diseases—Dr. F. G. Smith, Pennsylvania, chairman. On Medical Education—Dr. T. G. Richardson, Louisiana, chairman. On Medical Literature—Dr. J. J. Woodward, U.S.A., chairman. On Prize Essays—Dr. Grafton Tyler, D. C., chairman.

Voluntary communications will be presented by—Dr. John Curwen, Pennsylvania, On the Proper Treatment of the Insane. Dr. Nathan Allen, Massachusetts, On the Physiological Laws of Human Increase.

Secretaries of all medical organizations are requested to forward lists of their delegates as soon as elected, to the Permanent Secretary.

Any respectable physician who may desire to attend, but cannot do so as a delegate, may be made a *member by invitation*, upon the recommendation of the Committee of Arrangements.

W. B. ATKINSON,
1400 Pine street, Phila.

SOME OF THE SURGICAL OPERATIONS OF THE LATE DR. R. D. MUSSEY.—He performed the operation of lithotomy 49 times, and all the patients recovered but 4. He operated for strangulated hernia 40 times, and with a fatal result in only 8 cases. He practised subcutaneous deligation in 45 cases of varicocele, and all were successful. He operated four times for perineal fistula, twice for impermeable stricture of the urethra, and did a large number of plastic operations with the best results.

A NEW TREATMENT FOR COLLES' FRACTURE OF THE RADIUS,

WITH REMARKS ON A NEW LUXATION OF THE ULNA.

Being a Paper read at the recent meeting of the Medical Society of the State of New York.

By E. M. MOORE, M.D.,

PROF. SURGERY, BUFFALO MEDICAL COLLEGE.

It is more than fifty years since Dr. Colles called the attention of surgeons to the fact that fracture of the lower end of the radius was very often overlooked, and confounded with a mere swelling from blood, and the subsequent inflammatory effusions. The confusion of all salient points arising from this swelling, and the frequent absence of crepitus, especially when handled in a gentle manner, has served to perpetuate a faulty diagnosis. This is the more to be lamented, as the accident is one of frequent occurrence, and, when not restored with precision, is clouded with a doubtful prognosis. I say nothing of the ordinary appearance of this fracture—this is too familiar for repetition. The wrist carried backwards, the ulna downwards and outwards from the axis of the forearm, the hand inclined to the radius, the fingers flexed, all present an attitude which is well formularized by the "silver-fork." The fact that modifications of treatment have been proposed by many eminent surgeons since the time of Dr. Colles, serves but to show that our knowledge has, in some way, been incomplete. An opportunity to make a post-mortem examination, under very favorable circumstances, has so modified my own views, and I have acted upon them with such constant success, that I feel their correctness has received the test of an experimentum crucis.

In May, 1869, Mary Tumey, aged 45, in a paroxysm of insanity, threw herself from the third-story window of St. Mary's Hospital, striking the ground with both hands; receiving also a blow on the spine, opposite the second and third dorsal vertebræ. The spinal cord was crushed, and both wrists broken, producing Colles' fracture. She breathed but twenty minutes.

The condition was uncomplicated with any effusion, except a trifling amount of blood, or with any modification from muscular action.

The examination of the right arm was commenced by removal of the skin from over the wrist, leaving the fascia of the forearm undisturbed. Rotation of the hand did not produce crepitus.

The projection of the wrist backward was that of an extreme case of this fracture, and the ulna was carried well downwards and outwards from the axis of the forearm. On raising the fascia, the lower fragment was seen to ride the back of the upper one, or the main shaft of the radius, and to be placed at right angles to its natural position, while the hand was in a state of extreme flexion in relation to it. There was not the slightest impaction. The absence of crepitus was explained by the fact that the rough surfaces were not in contact. The fracture was transverse and the surface of the lower fragment, which was about half an inch in length, came in contact with the periosteal surface of the back of the upper fragment or main shaft. The entanglement permitted rotation, but not crepitus. The next step in the manipulation was to press the displaced fragment into its place. I was surprised to find a resistance which seemed like muscular action. This being manifestly impossible, the cause was again sought for by a repetition of the movement, when the same result was produced, giving an elastic rebound.

The solution was found in the peculiar position of the ulna, its luxation and ligamentous entanglement.

It will be remembered that the ulna does not articulate with the wrist-joint, but that its head, although covered with cartilage, and provided with a synovial membrane, and of course a complete joint surface, articulates with the triangular fibro-cartilage. The anatomists emphasize this arrangement so decidedly, that we are apt to forget the important fact of the articulation by the triangular fibro-cartilage on its distal surface with the wrist-joint. Thus the ulna has a mediate articulation with the wrist-joint, a fact of great practical significance. It will also be remembered that the fascia of the forearm is very much strengthened at its lower end, and that the extensor muscles run in grooves constructed from it, and that its transverse fibres, under the name of the posterior annular ligament, run across to the pisiform bone, some of them passing over the head of the ulna. The internal lateral ligament passes from the end and inner surface of the styloid process to the cuneiform bone. The triangular fibro-cartilage also subserves the purposes of a ligament, making an insertion in the pit at the base of the styloid process, but with a stronger attachment to the radius. The ulnar extensor runs in a sheath of the fascia, and as can be seen and felt upon the living arm, takes a course between the styloid process and head. But while it is really on the back of the fore-arm, it is so far upon its side that the tendon plays upon the side of the head and furnishes a lateral support. The tendon is just above the internal lateral ligament. The cause of rebound now became manifest; for the styloid process was so far projected as to catch the fibres of the annular ligament, and the ulna being prevented from rising, forced the wrist back. Various attempts at reduction were made at this stage of the examination. The ordinary plan of bending the hand toward the ulnar border of the fore-arm resulted in tightening the annular band on the styloid hook, and no pressure on the anterior surface of the ulna could cause its liberation, but, on the contrary, insured its retention. Simple extension also failed to relieve the entanglement and restore the luxation, but a movement described below was entirely successful, and when the parts were all replaced, the tendency to displacement was inappreciable. An incision through the annular ligament revealed the nature of the separation. The internal lateral ligament was torn away from its attachment to the styloid, by separating the scale of compact bony tissue composing its end and inner surface (the ligament proving stronger than the bone), thus leaving the styloid as a rough and ragged hook to hold the annular ligament. The attachment of the triangular fibro-cartilage to the styloid was also torn off, but the rent was through the cartilage, leaving a few tags at the pit. The complete severance of all ligamentous restraint permitted the ulna to bulge outward and downward; and as the hand is carried backward and upward, the styloid hook is moved forward and held at the pisiform bone by the annular ligament. The ulnar extensor was carried toward the radial side of the ulna. When the ulna became free from the annular ligament, its head was moved toward the radius, and through the fibro-cartilage, rested against the wrist-joint, thus holding the hand out at full length, keeping the fractured ends of the radius in apposition, and furnishing the best of all splints—an entire parallel bone, in place. Thinking it possible that the condition found might be peculiar, I proceeded at once to a similar examination

of the left wrist. The fracture was oblique in two directions. Commencing within a quarter of an inch of the wrist-joint on the palmar surface, the line ran back to three-fourths of an inch, inclining to the ulna. The position of the ulna was the same as on the right side; the rupture of the internal lateral ligament took place in the same way, carrying rather more of the bone tissue than on the right side. The triangular fibro-cartilage was torn out with similar tags and the annular ligament was folded into a similar cord, causing a rebound when the lower fragment of the radius was carried down into its place. The only point in which the two differed was in the line of fracture, which seemed not to bear the least upon the question of reduction or retention.

The fibres of the pronator quadratus were a little torn in both cases, but I could not perceive that there was any influence exerted by it or any other muscle or tendon in preventing reduction. As before stated, the autopsy exhibits a case of what may be termed an extreme condition of this form of injury.

It is altogether probable that fracture of the radius may occur with which there is no complication of ulnar luxation. In these cases, there would be but little deformity, and crepitus would undoubtedly be a matter of easy determination.

A good result with almost any treatment would also be probable. But a force competent to fracture the radius, if not expended, would generally be able to rupture the ligaments, in consequence of the immense leverage that the hand acquires with the head of the ulna resting mediately on the carpus. When the internal lateral ligament and triangular fibro-cartilage yield, the annular ligament becomes slipped over the head and on the styloid hook. In order to determine the succession of movement in the ligamentous rupture, I subjected the arm of the cadaver to a force gradually applied, after having made a fracture of the radius just above the wrist-joint. This was effected by strapping the arm firmly down and attaching a lever to the hand, then bending the latter well back with a slow but irresistible force. The hand began at once to describe a circular sweep upward, backward, and toward the ulna; in short, such a movement as would necessarily occur with the short fragment, held by the radio-ulnar ligament. The bulging of the ulna outward and downward preceded the rupture of the internal lateral ligament. But the fascia of the forearm lying on the ulnar head became stretched, and fibres of the annular ligament slipped over it. As the force was continued, a double snap, loud and sharp, was produced by the breaking of the internal lateral ligament and the triangular fibro-cartilage—apparently in the order stated. The end and internal surface of the styloid was broken off. The annular ligament at the same moment was caught on the styloid, presenting precisely the appearance shown by the autopsy.

If there should be an arrest of movement before ligamentous rupture, the difficulty is one of simple fracture uncomplicated with luxation of the ulna. The annular ligament, though drawn a little over the ulnar head, would not be likely to interfere with reduction. But when the internal lateral ligament and triangular fibro-cartilage give way, the displacement of the ulna assumes a definite shape, and in this resembles the other regular luxations which are determined by constant forces.

The autopsy and subsequent experiment render it evident that we have in the injury usually known as Colles's fracture, not a mere break of the bone, but a luxation, to deal with.

The displaced ulna is always noted, and surgeons have had various suspicions of ruptured ligaments. But it has not been regarded in the light of a luxation with a regular position, which must be rectified before replacement of the fracture should be made, and without which imperfect results are to be expected. This, I am convinced, is the key of the difficulty. Reduction of the luxation must first be made, and then the fracture is probably of all others the most insignificant. But no theory can be of much importance without the support of cases, and it has been my good fortune to have the results of my treatment subjected to tests sufficiently numerous to place the matter at rest as a practical plan. The mode of procedure is as follows:—

The patient may be etherized or not. An assistant holding the forearm of the patient, the surgeon grasps his hand, the right with the right, and *vice versa*. With the other hand placed under the forearm above the fracture, he is enabled to bring the thumb over the back of the ulna, the fingers wrapping around the radius. Traction is first made by extension, then drawing the hand laterally to the radial side, then backward, next keeping it held backward, and while making extension, it is swung toward the ulnar side, bending well laterally, when the extension of the hand is changed for flexion, thus describing nearly a semicircle in circumduction. The position of the hand grasping the forearm undergoes constant change, as it is the antagonist of the other hand in everything but the extension. As the backward position of the hand, when it is carried to the extreme ulnar side, is changed to flexion of the hand, the thumb of the surgeon rolls around the border of the ulna, and is below when the manœuvre is complete. The test of reduction is to be found by the presence of the head of the ulna on the radial side of the ulnar extensor.

The head of the ulna rests mediately, through the triangular fibro-cartilage, on the cuneiform bone, and is restrained from going backward by the annular ligament, holding on each side the tendons of the extensor minimi digiti, and the extensor carpi ulnaris, thus making a concavity corresponding in form to a socket. When it is pressed into this pocket, and the hand flexed so that the head is supported by the wrist, the position of the hand is also restored in its relation to the radius. As a result of the displacement of the ulna, the ulnar extensor is carried from its place above the styloid process to the opposite side of the ulna, in an extreme displacement, but sometimes remains above its centre. To disentangle the styloid and swing the tendon of the ulnar extensor over into its place, is the purpose of the manœuvre. The hand is drawn toward the radius, to pull off (by stretching) the annular ligament. The backward motion, accompanied with extension, renders the ulnar extensor tense, which serves to draw the annular ligament backward. This is effected by pressing the thumb upon the ulna. The circumduction carries the tendon over the side. Its character as a luxation is still further shown by the fact that the restoration is often accompanied by a snap both tangible and audible. If restored, the retention is effected by a compress and bandage of adhesive plaster. When the manœuvre described has been completed, the hand is flexed, and the thumb of the surgeon rests on the under side of the ulna. Its head appears on the back of the wrist, and corresponds with the opposite arm in every respect, except the swelling from blood effusion. As in the treatment of any other luxation, the effort should not be abandoned until the deformity is removed and the ulnar extensor in its place,—a fact that can be determined at once. The dressing I propose is intended to hold the head of the ulna up in its fascial socket, by bringing the weight of

the hand to bear upon the ulna to retain it home. If the thumb of the surgeon is kept under the ulna after reduction, it will be found that the weight of the hand is sufficient to keep it in place. As a substitute for the thumb, I place along the ulna, from the pisiform bone upward, a cylindrical compress about two inches in length, and about half an inch in thickness—in fact, a single headed roller. This is placed against the ulna, resting also on its radial border against the tendon of the flexor carpi ulnaris. A band of adhesive plaster of the same width is wrapped firmly around the wrist, and over the compress, extending downward to the extreme point of the radius, thus grasping the bones neatly and tightly. The ordinary rule of loose dressing on the first visit to a fracture is one that I distinctly reject. I propose to bring all the parts into close relation. The patient is allowed to cut the bandage along the back of the wrist in about six hours, if the swelling and pain seem to demand it. But I find it is not often done. The thickness of the compress raises the adhesive plaster so far from the anterior surface of the forearm that strangulation of the vessels does not take place. Moreover, the compress yields a little, and thus diminishes the pressure. A narrow sling passing under the compress, so as to bring the hand's weight to bear upon the ulna, completes the dressing. Indeed, even in the recumbent posture this should be done. The first recent case occurred in July of the current year, in a man thirty-two years of age, who received the injury to his wrist by a fall of fourteen feet. The patient was seen by two of my medical friends, Drs. Hovey and Rogers, of this city. The diagnosis was inferred, not only from the deformity, but was confirmed by crepitus. They applied the method of reduction described above, and had the satisfaction to find the head of the ulna appearing on the radial side of the ulnar extensor tendon. The compress and plaster were applied as described. I did not see the patient until the third day, when great swelling, in consequence of a firm renewal of the bandage daily, had resulted in the production of great pain. The patient being confined to his bed for other injuries received at the same time, the hand, unknown to Dr. Rogers, had been supported and carried toward the radial side. This resulted in some displacement. On the third day the surgical manœuvre, as described, was again employed, and the compress and bandage applied, but not so tightly, and then the hand allowed to hang down, supported by a sling under the compress. The treatment was continued four weeks.—*Oct.* 18. Called to see the patient, who had been at work five weeks. He performs the hardest kind of labor with ease (lifting heavy lumber). There is the evidence of a little thickening around the whole wrist, but not much. Says there is slight "soreness" at night. Result perfect.

However, a minute detail of cases is unnecessary. The same plan was adopted, as far as the dressing is concerned, but as several were seen at various periods remote from the time of fracture, and when union had taken place, requiring force for its separation, it was found necessary to add weight to the hand and maintain the treatment for a longer period of time.

The cases in order of succession were, Edmund Blohm, aged thirty years, whose case has been described. It was the first one that received the treatment in its simplicity, and the bandage was retained four weeks.

Mrs. Betsey Tod, æt. sixty-nine, was seen by Dr. Hillman, and treated by bending the hand downward toward the ulna, as commonly practised, and retained by an angular splint. At his request I saw the patient ten days afterward. Restoration had not occurred, and Dr. Hillman gave his opinion that no change had resulted from the dressing. The patient was etherized, and reduction effected at once. Treatment continued thirty days.

This patient is the only one in whom the result was in any way imperfect. The inflammation was rather unusual, and although the reduction was complete, the ligamentous repair was not as perfect as in the other cases and the ulna gradually slid away laterally, producing a consecutive luxation. This result admonishes us to extend the period of treatment when there is much inflammation.

Mrs. Sarah Wise, æt. sixty-nine, was treated with an angular splint four weeks. Great swelling and pain resulted, and continued until the time of reduction. I first saw her on the thirty-fifth day after the fracture. A good deal of force was necessary to effect the object, but it was accomplished by the hands alone. The swelling has continued far more than in any other case, but restoration is complete and the use of the hand returning. In no other case has the swelling or inflammation been more than trifling. The treatment was carried out for forty days, aided by the use of a shot-bag, weighing three-fourths of a pound, during fifteen days.

Mrs. Amanda Smith, æt. fifty-three, was not treated at all, as she thought it "was only a sprain." Not improving, but, on the contrary, following the usual course of the unreduced fractures, she grew worse and applied for advice. On the forty-first day she was etherized. The radius was so firmly united, that it required all the strength I could exert to break it off, bending the hand backwards. After the separation, the hand was swung into its place and retained by compress and bandage, aided by a shot-bag three-quarters of a pound in weight. This was used for fourteen days, and then the weight of the hand alone was relied on for fourteen days more. These cases all presented some difficulties, which would not generally occur. The time that had elapsed from the injury to the reduction rendered the restoration more difficult.

Miss Mason, æt. sixty, was the first case I saw immediately after the accident. I need hardly describe the case. Suffice it to say, that the condition was one of moderate severity; under the ether reduction was effected, and the dressing applied tightly, with direction to cut the strap on the back of the arm if it became painful. This was done in a few hours, but the plaster retained its position and was continued to the end of the treatment. On the thirteenth day the bandage was removed, and the direction given to use the hand. The restoration was rapid and complete.

Mrs. Van Ness, æt. fifty-two. Seen by Dr. Hillman on the day subsequent to the injury. She had been seen immediately after the accident by Dr. Swinburne, who diagnosticated the fracture, but the patient preferred to refer the case to her own medical adviser (Dr. Hillman), who also recognized the fracture, both by the deformity and the crepitus. He at once applied the treatment as above, which was continued until the eighteenth day. At this period I saw her for the first time and at once removed the dressing, directing the use of the hand. The industrious wife of a farmer found an abundant use for it, and took my advice literally, employing it at hard work. It has been a perfect result, indeed one of the most rapid in improvement.

The last case, Robert Crabtree, a laborer, æt. 35, had broken his wrist nine days before reduction, which was effected under ether with an audible snap. The strap and compress were removed on the thirteenth day.

Of the children, John Dean, æt. 14, was treated by Dr. Menzie, of Caledonia, after the plan proposed. The

dressings were removed on the twenty-eighth day. Charles Harman, æt. 8 years, dressed by Dr. Holman with the pistol-shaped splint. I was requested by the medical attendant to see the patient on the eighth day. It was plain that reduction had not taken place, but this was effected by circumduction. Treatment was continued four weeks—result perfect. Michael Kelly, æt. 9 years, reduced four weeks after the accident. Much force was required to break it over, but the reduction and retention were not difficult. Dressing removed on the fourteenth day. Two more cases of 15 and 17 repeat the same story.

Since my attention has been especially directed to the study of this fracture, I have become convinced that there are more cases of separation at the radial epiphysis during childhood than have been suspected. The cases of five children, from eight years of age to that of seventeen, in the practice of my medical friends and myself, occurring simultaneously with seven cases in adult life, are a larger proportion than is commonly supposed to exist between the two periods of life. But if the diagnosis is often overlooked, the restoration is more easy in children. The rounded character of the bones and general flexibility of the child's wrist conspire to render the reduction easy. Simple extension will probably answer in most cases. The popular notion, that every deformity is caused by "something out of joint," has, in these cases, more justification than usual. One lad of fifteen came to me after reduction by some of his companions, who pulled at it "because it was out of joint." Every case, except one, that has been treated by the method described may be said to be perfect. This phrase does not mean to exclude the tenderness and swelling incident to such an accident, but conveys a correct statement of the anatomical relations of the injured and separated part, including the radius and ulna. I very much doubt whether any comminution of the lower fragment, upon which much stress has been laid, would materially affect the result. When the ulna is in place the full length of the fore-arm is attained, and the traction on the muscle would allow the broken parts to come down far enough to permit the irregularities to become adjusted with more than usual facility. The extensor tendons, placed upon the stretch by the drooping hand, retain the broken fragments with neatness on the back, while the adhesive strap, drawn with decided force, brings them together laterally. The method is essentially painless after reduction.

The short period of time for continuing the treatment, which has been adopted in the recent cases, has been justified by the results, and has been entered on for two reasons: Motion as early as possible after ligamentous repair is a cardinal principle in the treatment of luxation, and therefore desirable in these cases. Moreover, the fractured surfaces are broad and nearly apposed, and are in cancellated bone. These considerations induced the trial of fourteen days as the standard of time, which has been fully justified by the results.

To the plan of direct extension, which has some strenuous advocates, I am disposed to attribute more successful terminations than to that of immediate lateral bending toward the ulna. For extension is the means of reducing luxations so generally, that it would be likely to prevail here, but I am satisfied that it cannot be relied on for maintaining the neat and close fit required for the ulnar head in its fascial socket. Apparatus will become relaxed, and if the extension yields, there is a tendency of the ulnar head to slide downward. This can be verified by merely removing the support from beneath the ulna after reduction. Hence the plan of bending the hand laterally, which has been the almost universal practice, is justified by its success in retaining the ulna; but the plan so often fails in the restoration, that we must believe it has generally been pulled into its place by extension first in the cases that had a successful termination. The shortening of the radius and the lateral twist of the hand have usually been explained on the ground of impaction of fragments. This is rendered unlikely by the well-known fact that the head is carried backward of the line of the radius. If impacted, the line of force should be the axis of the radius. But nothing can be more evident than the fact that this can never be the case. The doctrine is, however, fortified by cases. Erickson reports an examination of a case, twelve days after fracture, and found the lower fragment split and impacted to the depth of half an inch, so as to require some force for its separation. The piece was tilted upward and backward. Now I submit that the adhesion in twelve days would be sufficient to render the question of impaction a difficult one to determine, and as they (the lower fragments) were tilted upward and backward, they were moving at the moment of injury in a direction not to be impacted.

The absence of crepitus is easily understood in those cases where the fracture is transverse, and the broken surface of the lower fragment is brought in contact with the periosteum. And, indeed, rotation can be made readily, without crepitus, when there is a mere interlocking of broken surfaces.

I have made some measurements, both as tests of the fact and amount of displacement, which I have not known to have been made before. By placing a plane surface behind the elbow and the forearm at right angles to the arm, a measurement to the extreme point of the ulna and radius shows, in the normal condition, that the distance is the same. But when the radius is broken and the ulna luxated, a shortening of the radius takes place, of from a quarter to nearly three-quarters of an inch. At the same time the breadth of the wrist, measured by placing two plane surfaces on each side, is increased by the lateral bend of the broken radius.

Robert Crabtree measured:

Left radius	11¾	inches.
" ulna	11⅝	"
Width of uninjured side	2⅜	"
" injured side	3	"
After restoration at once	2⅝	"
Length perfect.		

Michael Kelley, æt. 9:

Length of radius	7⅜	inches.
" ulna	7⅜	"
Injured side, breadth	2 1/16	"
Uninjured	1⅞	"
Restored	Alike.	

Résumé.—The lower fragment is carried back over the radius, turned toward a rectangular position, and is not impacted. This accounts for the shortening of the radius and the bending of the hand to the radial side of the forearm.

The internal lateral ligament and triangular fibro-cartilage are usually broken, and when this occurs the posterior annular ligament is slipped over the head of the ulna and caught on the styloid process, which brings and holds the point to the pisiform bone. The first step in the treatment consists in the restoration of the luxation, when the treatment of the fracture becomes entirely subsidiary. When the ligaments are repaired, if the apposition is perfect, the fracture may be trusted in the use of the hand. It is a luxation and not fracture that we deal with.

THE USE OF SULPHO-CARBOLATE OF POTASH AND OF LACTIC ACID AS SOLVENTS OF CROUPOUS MEMBRANE.

By C. C. TERRY, M.D.,

NEW YORK.

Fred. E———, 4½ years, lived in the same house with an uncle's family from which a girl of about Fred's age, and his constant companion in play, had died in about 48 hours from the commencement of a disorder which was at first called "sore throat" and the next day "diphtheria." From the parents' account of the case, it seems to have been croup.

Ten days after the death of his cousin, Fred seemed less active than usual, inclined to mope, and ate but little.

The next day, November 30, 1869, the child coughed a little, and seemed so feverish that the mother became alarmed lest there might be diphtheria.

During my attendance upon another child in the family, I had occasionally romped a little with Fred and the cousin, and my first observation now was of his unusual paleness and sluggish locomotion.

The throat was brawny, no glands distinctly enlarged; pharynx tumid, and, as also the fauces, streaked with a whitish material, whose appearance suggested muguet, especially as the uncovered parts were not perceptibly glazed. At this time the skin was dry and unusually warm, the pulse accelerated (apparently by fright). No complaint had been made of any symptom on the part of the child.

The muguet-like material was not easily detached, and left a red and bleeding surface, without apparent loss of substance.

A microscopical examination exhibited many blood corpuscles—the normal proportion of white; an immense number of irregularly circular and granular bodies, many as large as blood-corpuscles, but most smaller, and many without granular contents (pus and mucous corpuscles); many flat polygonal and nearly circular nucleated epithelia of various sizes; masses of finely granular material, spread out in considerable areas; and masses of coarser reddish granular material: altogether answering to Beale's description (Mic. in Med.): "There is nothing very distinctive in the exudation effused upon the surface of the mucous membrane of the fauces in cases of diphtheria."

A solution of sulpho-carbolate of potassa dissolved the parcel. So I was induced to sponge the throat with the same solution. Ice-water shrinks and stiffens the exudation; warm water has little solvent effect, as ascertained in other cases.

In the evening the neck was less brawny, the pharynx less tumid, paler, and exhibiting but slight traces of the exudation. But I was only at the upper margin of the objective disease, for the voice had become raucous, the cough brassy, the cry constrained; tracheal respiration harsher, and some râles.

Undertook to follow the exudation into the larynx and trachea with the sulpho-carbolate solution, and for a short time with seeming benefit. The pharynx had been very tolerant of the sponge and solution, but the laryngeal sensibility had become so obtunded, that only a slight cough followed the introduction of the solution. This was not encouraging for the lower air-tubes.

Prescribed a dose of the sulpho-carbolate, to be taken every third hour (Sansom in *Practitioner*, July, 1869, p. 12). The child would take nothing but water and an occasional spoonful of beef-tea—not enough to count.

Dec. 1.—Slept last night. Pharynx clean, but still tumid and red. Voice more raucous; cough more croupy; respiration embarrassed, increased in frequency; face anxious.

Sulpho-carbolate locally, and by stomach every hour. Auscultation discovered no change. Ice over larynx and trachea, not against the exudation so much as the probable subjacent congestion, which of itself might be able to embarrass respiration.

Dec. 2. Larynx more desperately involved; inspiration loud and harsh, respiration harsh; dyspnœa; duskiness of eyelids and contour of mouth; voice extinct; no cough; perfect anæsthesia of pharynx and larynx. An emetic did not assist in clearing the air-tube.

In the evening, increment of the dangerous symptoms; inspiration and expiration stridulous; under the ear but little air could be heard entering the deeper tubes, and throughout most of the lung there was a silence, broken only by a frequent bronchial râle and an occasional normal respiratory murmur; general cutaneous anæsthesia, or better, perhaps, inattention, for the little fellow walked excitedly around on his bed, and seemed intent only upon getting air into his lungs.

Respiration 52 per minute; pulse about 140, diminishing and almost ceasing with each prolonged stridulous inspiration, increasing in force and frequency with the alternate expiration.

The knowledge that, in certain rare cases, at apparently the last moment, a portion of membrane has been expelled with saving relief, weighed but light against impending asphyxia; and tracheotomy, in a trachea already diphtheritic, offers at least a mitigation of the agony.

At this juncture I was glad to share the responsibility with Dr. Jacobi, whose large experience in tracheotomy for croup makes his assistance excellent; and his kind hand lifted me over the difficulties of the operation. Chloroform was administered: under it respiration was something easier.

It was necessary to open as low as possible, and the trachea was both deep and small.

In the course of the operation the anterior mediastinum was pricked, as was announced by a hissing and crackling of visible minute bubbles with each inspiration and expiration.

The introduction of the tube was followed by calm respiration, the pulse lowering but a few beats. No cough; no expulsion of membranous fragments; but crying caused some swelling up of muco-sanguineous material from time to time.

The feather excited no cough, but annoyed the child by embarrassing the respiration, and brought up considerable quantities of brownish, shreddy, and mucous matter, which, under the microscope, exhibited mucus, pus, and epithelial bodies embedded in a viscid, slightly opaque, and striated substance.

The child fell asleep, and was left under observation. In the course of the night I was informed of an increasing dyspnœa, which was relieved by more care in clearing the tube.

Dec. 3.—Early in the morning I received word that suffocative symptoms had suddenly set in. Having in mind that I had once lost a promising case by complete occlusion of inner tube, which the attendant had not courage to pull out, I hastened to the scene of danger.

Unfortunately, the only one of the tubes present at the time of the operation, which was of suitable size, happened to be a single one which, of course, the attendants must clear *in situ*. After substituting an appropriate double one, it was discovered that the obstruction was indeed a plug of brownish glutinous material. Brandy and beef-tea could now be taken. The

child walked about the floor, appearing quite comfortable; but auscultation discovered râles in the larger bronchial tubes, and, although there was no dyspnœa, the respirations were shallow, 40 per minute, and the pulse 120.

The feather brought up considerable fragmentary material, which exhibited, in addition to the appearances last mentioned, a great many slow-moving vibriones. The sulpho-carbolate solution was applied by the feather in the bronchi. By this time there was emphysema of the neck and upper part of the breast, extending to the axillæ. (See Dr. Graham Weir's case in London *Lancet*, Am. Edit., Dec. 1869, p. 654.)

The solution became inoperative; the feather neither excited cough nor brought up considerable portions of exudation, nor was its presence in the bronchi resented except as it interfered with the passage of the diminishing current of air. Respiration became more laborious, while auscultation discovered good respiratory sounds everywhere excepting in the larger tubes at the root of the lungs.

By Dr. Jacobi's advice I substituted lactic acid (Weber) for the sulpho-carbolate solution, having previously ascertained its positive solvent action upon the extracted fragments of exudation. For a time there was a little improvement; the feather was more useful; respiration was easier; the child took its brandy and beef-tea, walked a little on the bed or sat on its mother's arm, and seemed happier. As the evening set in, all the symptoms took a desperate turn; so by 8 P.M. dyspnœa was violent, face dusky, countenance anxious, lips purple, eyes glazed, pulse 160, small and wavering, respirations 55—60, inspiration short but labored, expiration prolonged and noisy. Vesicular respiration everywhere pretty distinct; a few moist râles and harsh sounds in the larger tubes. Percussion sounds good.

The bronchi, to the reach of a long feather, perfectly insensible, and I could gather but a few dryish fragments of the exudation, and these were afterwards found to swarm with vibriones. A teaspoonful of the lactic acid solution, poured through the tube, bubbled forth again with the next expiration.

Emphysema had extended to spine.

Death in five hours, preceded by semi-coma and muscular resolution.

One remark: the emphysema was inconsiderable, entirely subcutaneous, and could have done no mischief (even if the repeated physical examination had not demonstrated its probable absence from the thoracic cavity), for the tracheotomy tube offered a manifold larger entrance than the minute prick of the mediastinal tissue.

MANAGEMENT OF MANIA A POTU.—Prof. Rochester, of Buffalo, N. Y. (*Buffalo Med. Journal*), in a Clinical Lecture on *mania à potu*, states that when tincture of digitalis was first recommended in this disease, he strongly opposed it, but his subsequent experience in the use of it has been quite happy. A patient who had not been improving was given one drachm of tincture of digitalis, and 20 drops of tinct. capsicum, once in two hours; two doses were taken, and at the time of the third dose he was sleeping well. In another case in the city, digitalis succeeded where active agents had previously failed. The bromides of ammonium and potassium may be given in doses of 20 grs. as a nervous sedative, or valerianate of ammonia used, and as a rule, opiates in some form. If the stomach is unable to bear opiates, hypodermic injections of one-half a grain of morphine may be given, and in three hours be repeated if necessary.

Original Lectures.

CLINICAL LECTURES ON THE DIAGNOSIS AND TREATMENT OF

STRICTURE OF THE URETHRA.

By J. W. S. GOULEY, M.D.,

PROFESSOR OF CLINICAL SURGERY AND OF GENITO-URINARY DISEASES IN THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

LECTURE II.

TREATMENT OF INTRACTABLE STRICTURES. DIVULSION AND DIVULSORS. ILLUSTRATIVE CASES.

GENTLEMEN—This patient appears here again, in accordance with the promise I made to you at the close of our last meeting. You will recognize in him the man who was suffering from prolonged retention of urine consequent upon stricture of the urethra. I propose now to report upon the progress of the case, and endeavor to estimate the value of the mode employed for his relief, and to ascertain what, if any, advantage it possesses over other methods.

On the evening of the operation the patient had a slight chill, which was not, however, followed by fever. On several prior occasions, simple catheterism had, in his case, been followed by similar but even more severe rigors. On the following day his skin was warmer than normal and his pulse 100 to the minute. He was also suffering pain in the hypogastric region, from overdistension of the bladder, which was nearly as full as before the operation, though, during the night, he had passed, involuntarily, a considerable quantity of urine, and no catheter had since been introduced. At about mid-day, a gum catheter was passed and three pints of urine drawn; the instrument was then plugged and retained in position, that some might be drawn off every two hours without subjecting him to the pain of frequent catheterism; at about ten o'clock P.M. the bladder was completely emptied, and the catheter was removed. I would advise you to pursue this plan under similar circumstances, but the instrument should not be retained upwards of twelve hours. On the third day the patient passed some urine at will, but afterwards most of it was taken from him by means of the catheter, morning and evening, after which the bladder was injected with two ounces of tepid water.

A red and painful swelling had made its appearance at the extremity of the prepuce, from infiltration of a drop or two of urine through the connective tissue of the frænum which had been involved in the incision of the meatus,—the frænum in this case extends unusually far forward. This tumefaction of the prepuce increased until the fifth day, when fluctuation became distinct, and the abscess was opened. The same occurrence had been observed in an analogous case some years ago, and had led me to make the incision a little to one side of the frænum in several others, by which this accident was avoided; but in this instance it had not occurred to me to carry out the plan.

The urine has been drawn off, and the bladder injected twice a day regularly. The cystitis is improving on this account, and also because the source of obstruction has been removed. The organ is rapidly regaining its power of contractility, and the patient is now (the 7th day) able to empty it without the aid of a catheter. He gets up but once at night and four times during the day, and passes a normal stream of urine. The bladder

will be injected once in the twenty-four hours for a few days more. He has had no chill since the occurrence of the rigor on the evening of the operation. As the case was one of great emergency, and as it was necessary to proceed at once to its relief, there was scarcely time to investigate it so closely as I have since been able to do at leisure. You will remember that your attention was called to the puffiness of his lids and to his pallid and bloated face. Subsequently, his legs and feet were noticed to be slightly œdematous, and it was ascertained, on close questioning, that he had been subject to headaches, dizziness, and photopsia. All this led me to have his urine carefully examined. Here is the report of Dr. Curtis (Acting House Surgeon) who made the examination.

The urine was acid, with a specific gravity of 1011; it contained abundance of albumen,—due, however, to the presence of a considerable quantity of pus. Microscopic examination revealed the presence of hyaline casts.

We have now to cope with this additional serious complication, renal disease, which would have hastened to a fatal termination, had the patient's bladder remained unrelieved, and had rupture of the urethra and extravasation of urine occurred. But it may now be fairly said that he has taken a new lease of life; and if he continues to be prudent and sober, his kidney affection may remain quiescent for years. His urethra is rapidly losing its extreme sensitiveness, and is in fact quite tolerant of the sound, as you see by his present behavior under catheterism. Please to observe also that the instrument (No. 13) meets with no impediment whatever, and that it has fairly entered the bladder. The incision made near the extremity of the prepuce is covered with healthy granulations and will soon heal entirely. The necessity of using a steel sound, of the size just employed, once a week for life, has been urged upon him, and it is to be hoped that he will follow the advice. It is as near as we can come to curing his stricture.

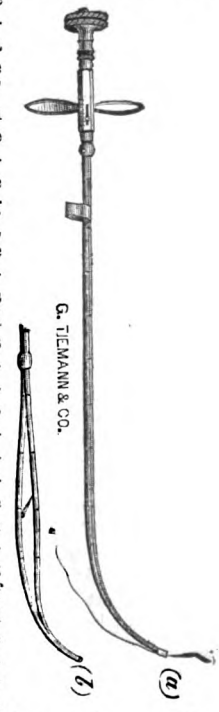
This very interesting and instructive case has furnished us an abundance of food for thought; I might entertain you an hour on either of the complications which have attended it, but other cases will, in good time, supply the same material: therefore, to-day I propose to occupy your attention with the merits of *divulsion* as a means of relief in narrow and intractable strictures, and to indicate to you, more in detail than I have done, the instruments proper to effect this. To cure intractable strictures without the knife has been, for many years past, the aim of progressive surgeons; to accomplish this, a great many devices have been proposed, and some of them have fallen into disuse, because they were found to be harmful and even dangerous; among them may be mentioned the caustic treatment so much in vogue in the times of John Hunter, Sir Everard Home, Whateley, Sir Charles Bell, Ducamp, etc. Others that have possessed merit have survived or have been resuscitated, and the necessary appliances have been subjected to modifications and improvements. Prominent among these is the method by divulsion, better understood and appreciated in our time than when the early "dilators" were brought forward. I will now briefly review, for your benefit, what has been done and what is being done in that direction.

In the early part of this century, Mr. Luxmoor, an English surgeon, employed a four-bladed instrument to "dilate" strictures; later, Mr. Weisse, a surgical instrument maker of London, constructed a two-bladed instrument (first used by Sir Astley Cooper) for the extraction of small calculi of the urethra and bladder; this suggested to him a three-bladed "stricture dilator"—a drawing of which appeared in his catalogue of surgical instruments published in 1831. Mr. Guthrie claims to have been the first to employ this "dilator." The instrument has an olivary point about equal to No. 5 of the English scale, and its blades, free at the extremity, are opened by means of a lever which is moved by a screw in the handle. But these instruments are too clumsy, too large, and cannot be applied to very narrow constrictions.

In 1847 appeared Dr. Michéléna's thesis on stricture, with a description and engraving of a "dilator" consisting of two blades, free at the extremity, and acted upon by a series of levers. In 1849 Mr. Rigaud published, in the "Gazette Médicale de Strasbourg," a description of a similar instrument, and the two are sometimes confounded. In Mr. Rigaud's dilator the blades slide upon each other while they are being opened, but in that of Dr. Michéléna they preserve their parallelism.

To Mr. Perrève of Paris is due the credit of having devised and employed a "dilator" with a short, delicate, conducting gum bougie attached to its extremity, and intended to penetrate very close strictures complicated with false routes. This instrument consists of two slender blades, between which rods of different sizes are introduced, according to the degree of dilatation the operator intends to make. His first "dilator" (without conductor) was devised as early as 1835. Many years later, Mr. Bernard Holt, of London, used the same instrument with some modifications, first only, as he supposed, to *dilate* the urethra. Two other surgeons, Richardson and Voillemier, have modified Perrève's instrument, but without altering the principle of action.

In the "Medical Times and Gazette," May 2d, 1863, will be found a description of an instrument devised by Sir Henry Thompson for the treatment of stricture of the urethra by "gradual distension at a single sitting," even "beyond the natural calibre of the canal." But rupture must have taken place, inasmuch as hemorrhage had always occurred after this so-called "gradual distension." The instrument has the merit of being very simple in construction, and, as I think it meets nearly all the requirements of a divulsor, I prefer it to the others. By means of a single lever, the two parallel rods are made to "separate so as to form a long oval or spindle-shaped figure," the greatest diameter of which will correspond to the seat of the stricture to be "dilated," and equal in circumference No. 18 of the English catheter scale, or even more. In the third edition of his treatise on stricture, etc., Sir Henry Thompson speaks of the instrument as suitable for the performance of divulsion. Believing the original dilator" to be too large for the treatment of very narrow strictures, I have had it considerably reduced in size, and have modified it so that it can be used with a conductor. The dimensions of the instrument I now show you (Fig. 5) are, 2 millimetres at the extremity, and 3½ millim. at the part susceptible of greatest expansion. Its diameters can be further reduced without any impairment to its



strength. Another important modification I have made, is in the blades, which, instead of being flat or guttered for the first two inches from the point, are cylindrical, so that the urethral mucous membrane cannot be pinched and torn in withdrawing the divulsor,—an accident that I have known to occur even when the precaution of not entirely closing the blades was taken. The curve of the instrument should not exceed one-fifth of the circumference of a circle three inches and a quarter in diameter.

If you have a predilection for any of the other divulsors, you may have them modified so that they can be used with a conductor. It matters little what kind of an instrument is employed, providing the principle of divulsion is carried out, and a safe and easy cure can be effected. Different operators will have their fancies and preferences; thus Amussat, Leroy d'Etiolles, Heurteloup, Civiale, Reybard, and Mallez have devised each his "dilator," and there are others too numerous to mention.

If you will study Mr. Perrève's cases, published in his treatise of 1847, you will notice that in nearly every one the occurrence of hemorrhage is reported; sometimes only to the extent of a few drops, generally more, depending upon the size of the rod introduced. Mr. Perrève did not *dilate*, as he claims, but did *tear* these strictures, hence his success. Mr. Holt, in the second edition of his book on the "Immediate Treatment of Stricture," speaks of "*a new stricture dilator*," but afterwards confesses that he preferred to "*split*" the strictures, as the partial dilatation he had before made had given rise to "stricture fever." He was perhaps the first to prove that there was laceration instead of dilatation, as he had had an opportunity to verify this in one of his own patients, at the dead-house, where there was found a longitudinal rent along the floor of the urethra at the seat of disease. Extensive experience has since taught the profession that nothing short of complete divulsion of the stricture will ensure success, and that after all it amounts to about the same thing as an internal urethrotomy; but it is a safer operation. Therefore Sir Henry Thompson's precept of *stretching* as much and *tearing* as little as possible might well be reversed, and I will venture to say to you, *tear* as much and *stretch* as little as possible, and your results will be all the better.

Do not deceive yourselves by believing that the urethral mucous membrane is only stretched, and that the part torn is the inodular substance in the sub-mucous tissue,—an idea recently advanced. I believe that the mucous membrane is nearly, if not always, involved in organic stricture; it should be, and is torn by the divulsor. Union by granulation takes place, and the mucous membrane grows over the cicatricial splice precisely as does the skin over a cicatrizing ulcerated surface. Hence the necessity to continue indefinitely the periodical introduction of large-sized instruments. Never neglect to recommend the use of the sound for ever after this or any other method of treatment of narrow strictures of the urethra. The exclusive advocates of divulsion promise too much: beware lest you fall into that error. Prudent and judicious surgeons should not be wedded to any particular method of treatment, but should adopt whatever plan seems best suited to a given case. It requires more judgment to decide upon the mode of treatment best adapted to a particular case, than skill to carry it out.

Now come two very important practical questions: 1st, to what class of cases is divulsion applicable; and, 2d, where is it contra-indicated? The second question had better be answered first. It is not, as a general rule, to be used in narrow traumatic strictures, neither in obstructions complicated with extravasation of urine, nor in the dense intractable constrictions of the pendulous portion of the urethra; but it is known to answer well in nearly all cases of coarctation situated in the scrotal and perineal portions of the urethra, and those which do not possess the elements described among the contra-indications.

It only remains for me to relate to you some illustrative cases, treated by divulsion, in my own practice, and then I have done for to-day. I have arranged them in groups, that you may the more readily seize the points which they teach.

The first group is intended to show that divulsion and not dilatation takes place when an attempt is made to enlarge suddenly a strictured urethra from within, and that the mucous membrane as well as the sub-mucous tissue is torn. Cases II. to V.

The second, that divulsion can be effected by the cautious and gentle use of conical sounds. Cases VI. to IX.

The third, that divulsion of certain strictures in the pendulous portion of the urethra is occasionally followed by fair results. Cases X. to XII.

The fourth, that divulsion is sometimes necessary in strictures that have been dilated to a considerable extent, but in which catheterism is followed by rigors and other discomforts. Cases XIII. to XVII.

The fifth, divulsion without conductor. Cases XVIII. to XXI.

The sixth group, divulsion with conductor. Cases XXII. to XXXII.

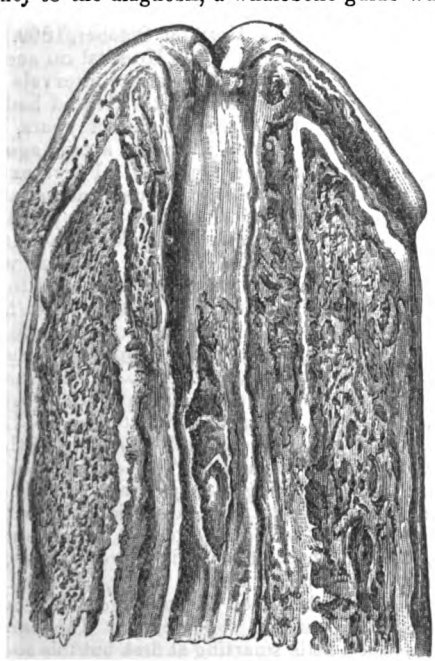
Group 1st.—Consists of four cases in which the urethra was examined with the greatest care after death.

Case II.—During the spring of 1868, I was summoned to the hospital at night, to see a man about 45 years of age, who had been suffering from retention of urine of thirty-six hours' duration. This was the consequence of a stricture of many years' standing, which had been treated, at irregular intervals, by dilatation. When I arrived at the hospital I learned that repeated trials to relieve him had been made, but with negative results. I found the patient under the influence of ether, while the House Surgeon was making an attempt, with a filiform bougie, to get through the obstruction; and the patient was bleeding considerably. Exploration with bulbous bougies revealed the existence of an extensive false passage, and also of a narrow stricture at the bulbo-membranous junction, through which a No. ½ whalebone bougie was passed, and over this Nos. 4, 5 and 6 tunnelled sounds were introduced and then Sir Henry Thompson's "dilator;" afterwards a silver catheter, No. 10, was passed, and one and a half pints of bloody urine drawn. He died on the following morning, about eight hours after I saw him. On post-mortem examination, the bladder was found greatly hypertrophied and inflamed, and the ureters and kidneys were in an advanced state of disease. In the urethra there was a false passage four inches in length, extending from about three inches of the external meatus to the prostate. The orifice of the false route was upon the floor of the canal, a little to the left of the median line, and was large enough to admit a No. 6 instrument. A number of short longitudinal rents were found through the mucous membrane at the seat of the stricture, mainly on the floor of the urethra. Divulsion was not done here as a means of cure, but merely to make way for the introduction of an evacuating catheter; he was in a hopeless condition, but it would scarcely have been humane to have allowed him to die unrelieved, and surely the death is not chargeable to the operation.

Case III. (Bellevue Hospital, May 27th, 1868.)—Wm. L., aged 32, was received into the hospital on

account of dysuria from a stricture (4½ inches down) of seven years' standing. He had had numerous attacks of retention of urine, and had been suffering much from dribbling. His urethra was unusually sensitive. Dilatation failed, and divulsion without guide was resorted to, and No. 10 sound passed. Four days after the operation he had rigors, and was extremely nervous and sensitive. On the fifth day he became delirious, and died pyæmic. The autopsy was made on the following day. A number of secondary abscesses were found in the lungs. In both kidneys there were also several abscesses. The pelves of the kidneys and the ureters were considerably dilated, and contained some slimy dark-colored pus. The bladder had undergone concentric hypertrophy, and its mucous membrane was in a state of chronic inflammation. The urethra having been laid open along its upper surface, a number of oblique and longitudinal slits or rents were found mainly upon its floor at the seat of obstruction, and extending backwards to the bulbo-membranous junction. The rents were from $\frac{1}{16}$ to $\frac{1}{4}$ of an inch in length, and involved the mucous membrane, which was somewhat thickened.

Case IV. (October, 1869.) G. P.—I was called to the medical wards of the hospital, to examine this patient and to relieve him of supposed retention of urine of two days' standing. The man was thirty years of age, and was suffering from rheumatic arthritis; his first seizure of rheumatism had come on twelve years before, and he had had in all six attacks. He stated to me that he had no desire to pass water, and had experienced none for two days. His mind seemed clear, and he conversed well. He had had gonorrhœa many years before, and had not, for several years, voided a full stream of urine. There was neither pain on pressure nor dulness upon percussion in the hypogastric region. Examination with bulbous bougies revealed a constriction, through which No. 2 could not pass, one inch and a half from the external orifice. As it was desirable to pass a catheter to give precision and certainty to the diagnosis, a whalebone guide was first



introduced, and over it No. 3 tunnelled sound, and then No. 4; a little hemorrhage ensued, and the retention catheter was passed, but only half an ounce of high-colored urine flowed. I then expressed the opinion that it was without doubt a case of suppression of urine, and advised dry cups and hot fomentations to the lumbar region, and a diluent drink, but not more than an ounce of urine was passed in the three days which he survived. Two days after I saw him he showed symptoms of uræmia, and soon became comatose. Post-mortem examination showed his kidneys to be granular and much contracted, but his ureters and bladder were healthy. The urethra was slit open, and you see that at the seat of stricture there is a longitudinal rent of the mucous and submucous membranes along the floor of the urethra, and about one and a half inches in length; this rent, with the exception of two slight bands which extend across its middle, is nearly as straight and almost as sharply cut as if it had been done with the blade of a urethrotome. (Fig. 6.) Divulsion was not here resorted to as a means of cure, but of diagnosis, for if the case had been a proper one, internal urethrotomy would have been employed in preference.

Case V.—Edw. K., aged 60, had had a number of attacks of retention of urine, and had for a long time been able to pass but a very small jet of urine. He was brought to the hospital with a fracture of the left thigh, and was at the time suffering from dribbling of urine, and no instrument could be introduced. I found a stricture 5½ inches down, which admitted but a capillary bougie. Divulsion was done with the modified Thompson's instrument. Hemorrhage moderate. No. 15 sound once a week. In the course of two months the fracture united and he was up, but afterwards became bedridden. He complained of headache, was seized with vomiting on several occasions, and finally came a low muttering delirium with increase of habitual tremor. The heart and lungs were normal, but the pulse was feeble, irregular, and intermittent. No organ could be fixed upon with certainty as diseased. He died three and a half months after the operation. The autopsy revealed a low grade of peritonitis, the abdominal viscera were glued together by recent lymph as well as old adhesions; no other lesion was observed. There had been no abdominal pain or tenderness during life. Ureters normal. The bladder was a little thickened. Prostate slightly enlarged. The divulsed portion of the urethra extended from the point of obstruction to one and a half inches backwards, and was one-eighth of an inch more in circumference than the healthy canal in front. Traces of several longitudinal rents were observable on the floor of the urethra, but showed firm cicatrization.

Group 2d.—I have already told you that divulsion could be accomplished either by the successive introduction of conical sounds beginning with small ones, or by means of instruments consisting of two parallel halves which can be separated either by a lever or set of levers acted upon by a screw at the extremity of the handle, or by rods which are introduced between the segments of the divulsor. The four cases I am about to mention will serve to illustrate the manner of proceeding with the first-named method.

Case VI.—C. H. H., a gentleman from the West Indies, aged forty-two, called upon me, three and a half years ago, to be treated for a stricture of twenty years' standing. He had been suffering for several years from painful and frequent micturition, and was straining a great deal to pass only an exceedingly small stream of urine, or sometimes a succession of drops. He had, on numerous occasions, been catheterized with small bougies, but his bladder had never been entered. His medical attendant gave him a small

flexible instrument that he might pass it himself; but he became extremely nervous, and his urethra was so irritable that he feared to make the attempt. In that state he came to me. On examination it was found that the smallest bulbous bougie would not enter a constriction situated in the sinus of the bulb. No. 1 English flexible bougie also failed to pass, but I succeeded with a slender whalebone guide, and introduced over this conductor the smallest of my tunnelled sounds, then a second, and finally a third. He was so nervous and irritable that I concluded to complete the operation at another sitting, and ordered a hip-bath, some quinine, and a diluent drink. He reported himself in three days, and the manœuvres resorted to before were repeated until a No. 12 could be introduced. Hemorrhage to the extent of half a drachm occurred. At the third sitting, wishing to pass still larger instruments, I had to make a free division of the external orifice, which had become painfully stretched on the passage of No. 12. After this Nos. 14 and 16 were introduced. He had no chill or fever after either sitting. The patient has remained well ever since, but an instrument (No. 14) has been introduced, for the first year once a week, but subsequently only once in two or three months. I saw him a few weeks ago, and he was enjoying excellent health.

Case VII.—On the 19th of October, 1866, F. R. applied to me, complaining of dysuria from stricture consequent upon a gonorrhœa contracted fifteen years previously, and aggravated by another clap caught fourteen years after the first. He had had a retention of urine, two years prior to my seeing him, which was relieved by the catheter. Exploration with the "bougie-à-boule" showed a stricture within the external orifice which would not admit No. 10, and another, 5½ inches back, through which only No. 1 would pass. An elastic English bougie, No. ¼, was introduced into the bladder and a tunnelled sound slid over it; after moderate pressure the sound passed the stricture, and was followed by others up to No. 6.

On October 22d, Nos. 6 and 7, and then successively Nos. 8, 9, and 10 steel sounds were passed; this was followed by a slight hemorrhage. Diluent, rest, etc.

On Oct. 26th, No. 11 could not be tolerated by the constriction near the external orifice; on this account, a free incision was made with Civiale's "bistouri caché," and then 11 and 12 were introduced into the bladder. On the 28th, No. 15 was passed. The sound was introduced at intervals of a week at first, but afterwards only once in six weeks or two months. He has since had another gonorrhœa. He called about a month ago (over three years after the operation), and his instrument was passed with ease.

Case VIII.—Wm. D., aged 70, was admitted into the hospital on May 10, 1867, with retention of urine of twenty hours' standing. He said he had been suffering from stricture of the urethra, from gonorrhœa, for forty years, and that he had been treated by dilatation on several occasions. He had contracted another gonorrhœa seven years prior to his coming to the hospital, since which attack his stricture had given him more trouble; and he had had several retentions. On examination, his bladder was found greatly distended, and fruitless attempts had been made to relieve it. The bulbous bougie revealed a stricture 5¼ inches from the external orifice, through which only a capillary spiral whalebone bougie could pass. Upon this conductor Nos. 4, 5, and 6 conical tunnel'ed sounds were successively introduced; the stricture, thus far only stretched, was divulsed by the passage of larger conical instruments to No. 12. A gum catheter was then passed, and three pints of urine drawn. The bladder was found to be atonied, and was treated accordingly. Sounds were used every few days, up to No. 15. He was discharged on June 1st, 1867, in excellent condition, and was passing a good stream of urine at normal intervals.

Case IX.—(Bellevue Hospital, August, 1867.) J. McM. Narrow stricture three inches from the external orifice, from gonorrhœa and from a bruise of the urethra. Several retentions, unsuccessful catheterism, false passage, dysuria, dribbling from overflow, retention. Divulsion upon whalebone conductor, with tunnelled sounds. Instruments introduced to No. 8, and subsequently increased. Good result. Case XII. is a good illustration of successful divulsion with conical sounds, after recontraction had followed the use of the two-bladed divulsor.

Group 3d.—Three cases of stricture in the pendulous portion of the urethra treated by divulsion.

Case X.—(March, 1869.) R. S. P., a gentleman forty years of age, came to consult me for a stricture of long standing, with urinary fistulæ. I was about to perform upon him the external perineal division for an obstruction 4½ inches back, but found that only No. 4 bulbous bougie could pass a stricture 2½ inches from the meatus; I therefore divulsed it freely with the modified Thompson's "dilator," and was then able to go on with the proposed operation. In the course of six weeks he left the city, after having learned to pass for himself a No. 12 sound. I heard from him four months subsequently, and he was doing well.

Case XI.—(Bellevue Hospital, April, 1869.) F. B., on whom I had performed external urethrotomy for a stricture in the perineal portion, and, some months after, internal urethrotomy for a constriction 3½ inches from the meatus, had neglected the use of the sound and had committed all sorts of excesses, reappeared eight years afterwards with fistulous openings and a very tight stricture at the seat of the last operation; for this I tried divulsion with Thompson's instrument without guide, after having dilated the coarctation to a sufficient extent to admit the divulsor. In about two months he was discharged from the hospital, and was passing No. 14 sound.

Case XII.—(Bellevue Hospital, October, 1869.) K. P., aged 38. This man entered the Hospital on account of dysuria, with constant dribbling in the intervals of micturition, which was very frequent. He had had five or six gonorrhœas in the space of eighteen years, but did not suffer in consequence till about a year ago, when symptoms of obstruction appeared. I first examined him on the 16th of October, and found a dense stricture 2¾ inches from the external orifice. At a point corresponding to the constriction, an induration extending back half an inch could be distinctly felt from without. A whalebone conductor was introduced, and tunnelled staff No. 4 passed down to the stricture, but failed to make any impression upon it. No. ¼ elastic bougie went through, and was retained in position three hours, and No. 1 was substituted, then No. 1½, and finally No. 2. Complete divulsion, to No. 18, was afterwards done with the modified Thompson's "dilator." No. 12 sound was used every second day until November 9th, when No. 10 only could be passed. The tendency to recontraction was becoming stronger, and on November 22d it was decided to repeat divulsion, but with conical sounds instead of the two-bladed instrument. Accordingly No. 5 was introduced; it was firmly grasped at the strictured point, then 7, 10, 12, 14, and 16 were cautiously passed. Free hemorrhage followed. No chill or other accident supervened. The passage of urine caused a little smarting at first, but this soon subsided.

Before the last divulsion he suffered from too frequent

micturition, but ever since he urinates, in a good stream, only four times in the twenty-four hours. No. 13 sound is now introduced once a week with facility, and the induration at the point of stricture is subsiding.* See Case IX.

Group 4th.—Five cases, in which dilatation could not be tolerated, successfully treated by divulsion.

Case XIII.—(July, 1867.) E. T., aged 28, had been under a six months' course of gradual dilatation for a stricture 5⅜ inches from the external orifice, but the coarctation remained extremely sensitive, and though it had been dilated to No. 12, showed a strong tendency to recontract whenever the use of instruments was discontinued. On that account divulsion was performed with Sir Henry Thompson's "dilator." The external meatus, which had been dilated to No. 12, became painful, and was accordingly divided, and sounds were passed at intervals of three days to No. 15, with scarcely any pain. The patient has remained well ever since.

Case XIV.—(Oct., 1867.) D. McN., aged 30. Stricture of three years' standing, 4¾ inches down, dilatation to No. 12. Sensitive urethra. Divulsion with Thompson's instrument. Sounds to No. 15. Urethra tolerant. No relapse.

Case XV.—(January, 1867.) Mr. ——, aged 40. Stricture, of long continuance, in bulbous portion. Dilatation insupportable, chills, etc. Divulsion with Thompson's instrument. Full-sized sound well borne. Good result.

Case XVI.—(January, 1869.) James C., aged 51. Stricture, of twelve years' standing, 5¾ inches down. Several courses of dilatation. Relapse from neglect. Dysuria. Failure of continuous dilatation. Divulsion, Thompson's instrument. No. 14 sound. Good result.

Case XVII.—(December, 1869.) Thomas W., aged 50. Old stricture. Retention and extravasation of urine four and a half years ago. "Perineal section." Silver catheter retained five months. Extremely irritable and sensitive urethra. Dysuria. Catheterism followed by rigors. Divulsion upon conductor (Thompson's instrument). Catheterism better tolerated. No more rigors. No. 12 every third day.

Group 5th.—Divulsion without conductor. The cases in this group were treated before I had made the modifications in Thompson's instrument.

Case XVIII.—J. M., a gentleman of excellent constitution and good habits, aged 38, was brought to me by my friend Professor J. S. Davis, of the University of Virginia, on the 26th of November, 1867. The patient was suffering from dysuria consequent upon a stricture of the urethra of ten years' standing. He had been for several days on the verge of retention of urine, but the trouble was kept at bay by rest, hip-baths, diluent drinks, opium, etc. I found him nervous, agitated, and in constant dread of complete retention. Urine had been dribbling from him for two or three days. He had made up his mind to undergo a cutting operation, if he could not be relieved otherwise. On exploration with bulbous bougies, a stricture was recognized in the region of the bulb, through which nothing would pass but a spiral whalebone bougie half a millimetre in diameter; over this a No. 4 tunnelled sound was introduced, and the canal was farther enlarged to No. 6, then a gum catheter was introduced and retained for ten hours. On the following day divulsion was performed with Thompson's instrument. Hemorrhage to about a drachm followed, and No. 12 sound was passed without difficulty. Every second day a larger sound was used, until No. 18 could easily reach the bladder. He left the city within two weeks after the operation, taking with him Nos. 16 and 17, which he has introduced once a week ever since. He now passes a full stream of urine at normal intervals, and is enjoying excellent health.

Case XIX.—(Feb., 1868.) James H., narrow stricture, 5½ inches down. Retention, relieved spontaneously. Dysuria. Preliminary dilatation with tunnelled staff upon conductor. Divulsion at the same sitting, with Thompson's dilator. Little hemorrhage. No. 11 sound. Slight rigors on second and fourth day. Sounds to No. 13, to be continued once a week. Good result.

Case XX.—(June, 1868.) Aug. M., aged 28, narrow stricture, of four years' duration, 5¼ inches down. Failure of dilatation. Dysuria. Preliminary dilatation, then divulsion (Thompson's "dilator"). Hemorrhage trifling. No. 14 once a week. Was out every day from date of operation.

Case XXI.—(Dec., 1868.) Patrick H., aged 35. Stricture of several years' standing. Failure of dilatation. Divulsion. (Thompson's "dilator.") Hemorrhage about a drachm. No. 12 once a week. Patient still under observation; has not used instruments for nearly a year. No relapse.

Divulsion should be performed with a guide whenever the stricture is very narrow, or there exist false passages. To effect this, I have a preference for the filiform whalebone bougies, because they can generally be passed with readiness where other conductors fail. When a tight stricture is encountered, it is usually recommended to tie in a delicate gum catheter or bougie, for twenty-four or forty-eight hours, in order to make way for the divulsor, but the introduction of such instruments is sometimes impracticable; the stricture is then considered impassable, and in the event of retention of urine the bladder is punctured, or else the external perineal division is done. I think that these extreme measures can frequently be set aside if the capillary guide and small conical tunnelled sounds are employed, as by this device sufficient dilatation can be made for the passage of a divulsor, and at the same sitting the bladder can be relieved and the stricture divulsed.

Group 6th, consisting of eleven cases, will show the results of the method just referred to, as applied to very close strictures. Preliminary dilatation was made, in every instance, with conical tunnelled sounds, and immediately after, divulsion to No. 18 was done by substituting the modified Thompson's "dilator" for the tunnelled sound, without removing the conductor.

Case XXII.—(March, 1869.) Dr. ——, aged 28, sought my advice for a stricture of long standing which had at times given him a great deal of trouble. He had been treated in England, and had afterwards, at irregular intervals, introduced sounds for himself, but the instruments had probably not entered the bladder, as his urethra was very sensitive and the stricture very narrow. The obstruction, seated in the region of the bulb, would not receive the smallest "bougie-à-boule." After a great deal of hesitation he submitted to the operation of divulsion, preliminary dilatation having been made with the tunnelled sounds. The hemorrhage was moderate. Sounds were then passed to No. 14. At first micturition caused some smarting, but no accident occurred, and he went away carrying with him a sound of proper curve which he promised to use once a week. He was heard from a few months ago, and was doing well.

Case XXIII.—(April, 1869.) Chs. V., aged 35. Supposed impassable stricture of seven years' standing, five inches down. Dysuria. Very frequent micturition. Extremely sensitive urethra. Preliminary dilatation

* *March 22d*, 1870.—The sound is still passed, and, thus far, the stricture shows no tendency to recontract.

with tunnelled sounds upon conductor and divulsion at the same sitting. Hemorrhage moderate. No. 14 sound once a week.

Case XXIV.—(April, 1869.) Harvey E., aged 28. Very tight stricture 5½ inches back. Retention of urine. Preliminary dilatation and divulsion at the same sitting. Slight hemorrhage. Gum catheter retained twelve hours. No. 12 sound once a week.

Case XXV.—(July, 1869.) F. F., aged 40. Narrow stricture of many years' standing. False passage. Urethra excessively sensitive. Catheterism very difficult. Preliminary dilatation and divulsion. Hemorrhage about two drachms. Sounds to No. 17. No. 10 on the next day, but no instruments could afterwards be passed, on account of increased sensitiveness of the canal. Abscess in perinæum. Urinary fistula.

Case XXVI.—(June, 1869.) Matthew K., aged 52. Stricture of long standing, 3½ inches back. Fistula in perinæo. Dysuria, etc. Tunnelled sounds and divulsion at the same sitting. Sounds to No. 11. In the course of a month urine ceased to flow through the fistulous opening. Not heard from since.

Case XXVII.—(July, 1869.) Albert M., aged 26. Stricture 5½ inches down, with perineal fistula. Was treated by dilatation about a year and a half previously, but from neglect the difficulty has returned. Dysuria becoming troublesome, he again applied for treatment. Tunnelled sounds, and divulsion. Sounds to No. 15, once a week.

Case XXVIII.—(October, 1869.) John H., aged 46. Very narrow stricture of six years' standing, 6 inches down. Retention of urine. Cystitis. Hematuria. Dysuria. Very great frequency in micturition. Dribbling. Failure of ordinary catheterism. Tunnelled sounds. Divulsion. Slight hemorrhage. No. 16 once a week. Micturition less frequent. Cystitis better for a few weeks, but recurred in the most violent form. Death three and a half months after the operation. Pyelitis (calculous?). No autopsy.

Case XXIX.—(February, 1870.) J. McG., aged 36. Tight stricture, 6½ inches down. Retention of urine. Failure of ordinary catheterism with fine bougies. Tunnelled sounds, and retention of catheter. Three pints of urine drawn off. Divulsion to No. 18. Hemorrhage moderate. Chill on following day, but no further trouble. No. 14 sound once a week.*

Case XXX.—(February, 1870.) J. S., aged 53. Stricture 4¾ inches down, supposed to be impassable, of fourteen years' standing. Dysuria. Micturition every half hour. Failure of many attempts at catheterism. tunnelled sounds with conductor. Divulsion. No. 10 sound once a week. Micturition five times in the twenty-four hours in a good stream.

Case XXXI.—(March, 1870.) Joseph C., aged 43. Stricture of nine years' standing, 5 inches down, supposed to be impassable. Dysuria. Micturition every fifteen minutes. At times dribbling. Catheterism followed by rigors. Whalebone conductor. Tunnelled sounds. Divulsion. Hemorrhage one drachm. Sound No. 14. Rigor on the following day, but no accidents. Micturition six times in the twenty-four hours.

CASE OF TRAUMATIC STRICTURE WITH FISTULA.

Case XXXII. (April, 1869.) George H., aged 28. Fracture of the pubes with laceration of the urethra. Retention in three days relieved by the catheter. Urine bloody for a week. Several retentions and finally abscess in upper part of thigh and urinary fistula. Dysuria. Micturition every fifteen minutes. Failure of catheterism. One year after the injury, stricture at bulbo-membranous junction, which would only admit No. ½. Tunnelled sound No. 3, then the modified two-bladed divulsor. Gum catheter retained for twelve hours. Sounds to No 13, once a week. In five weeks fistula healed. Micturition normal.

You will observe that, among the thirty-two cases treated, there were twenty-six successful results, one failure, and five deaths. Of the five deaths, two occurred at the end of three and a half months, and were not attributable to the operation (Cases V. and XXVIII.); one patient died of suppression of urine, with which he was affected before the operation (Case IV.); one died eight hours after divulsion, but would not probably have lived any longer had he been let alone (Case II.); and one death only (Case III.) was hastened by the operation, pyæmia having ensued.

I believe divulsion possesses great advantages over cutting operations in properly selected cases, and that it will be often resorted to where internal and external division has heretofore been employed; but it can never entirely supplant these and other methods, though it will probably continue to occupy a very prominent and important position among the surgical therapeutics of stricture of the urethra.

* Cases 29, 30, and 31 have been added to complete the series.

Progress of Medical Science.

HYPODERMIC USE OF ERGOT IN INERTIA OF THE UTERUS.—Dr. H. Ernest Schmid, of White Plains, reports the following:—Mrs. H—— was taken in labor on the second day of March. She did not send for me until 3 o'clock A.M. the following night. Her pains had been short but severe, recurring every 2 or 3 minutes. She felt them solely in the back, experiencing no down-bearing sensations whatever. I was the more astonished to find, on examination, labor far progressed, the posterior fontanelle occupying the centre of the inferior strait—the external parts well relaxed and dilatable, so as to admit of a quick completion of the remaining act of delivery. But three hours later the state of things was the same, with this one disagreeable difference, that she had no more periodical short *pains*, but only a constant severe pain in the small of the back, with not the slightest contractile action in the womb. By kneading the abdomen well with my left hand, and titillating the edges of the os with my right index finger, I could only effect a feeble contractile motion in its fibres, which again quickly subsided. Cold produced no better result. From a casual conversation I had had with her former medical attendant, who had delivered her of her first child at some distant town, I had learned that, after three days' ineffectual labor, marked by this same agonizing pain in her back, without uterine contractions, he had been obliged to extract the child with instruments, from no cause except this persistent inertia of the womb. I administered fluid extract of ergot to her, but it was of no avail whatever. While she was taking 3 drachms of it, two hours had elapsed. Then it occurred to me to give it hypodermically. I injected at once 25 minims of it in the upper outer part of her right thigh. In the course of 20 minutes a vigorous action of the uterus commenced, and with three very strong pains a fine female child was born in about 10 minutes. The placenta having been removed with very little assistance, the uterus contracted readily on itself. Although the ergot had been given by the mouth, the way in which the symptoms developed themselves strongly inclines me to the opinion that the final effect was due to the subcutaneous administration of the drug.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

QUACKERY AND THE PRESS.

THE ignorance of medical matters by the people is nowhere more manifest than in the continued countenance and support which is given by them to every shape of quackery. It certainly seems strange that even the intelligent portion of the community, composed of lawyers, clergymen, philosophers, statesmen, men of letters, and scholars, who are well enough informed on almost every other matter to prevent them from straying outside the bounds of common sense, should not only deliver themselves body and soul to the most ruinous of all humbugs, but should lend even the weight of their influence to its propagation. Men who would reason calmly on any other subject, and would decline to render an opinion concerning any point they do not understand, are ever ready to discuss a medical problem, and proclaim their views with all the boldness of rightful authority. What, however, appears still more remarkable is, that the masses should be so influenced by such opinions, in contradistinction to those who are justly entitled by education, experience, and observation to give them. Such, however, is the fact, and we must accept it.

The more influential an individual is, provided he be not a well educated physician, the more potential are his assertions in favor of a nostrum. If a popular clergyman, lawyer, lecturer, writer, or educator recommends a soothing syrup, or testifies to the wonderful properties of some throat balsam, chest invigorator, or the like, it is sufficient to insure its success. No one questions his right to an opinion on the premises, and the majority of his admirers admit his conclusions. But this has always been the case since quackery had an existence, and there has seldom been wanting even the influence of royalty to support the pretenders.

The most powerful auxiliary of quackery is undoubtedly the press;—in fact, the nostrum-venders depend so entirely upon it for support in the way of advertising themselves that without it they could do nothing. The press, in its turn, as a matter of emolument, opens its columns freely and unreservedly to any who choose to pay the cash price for such a privilege of an insertion. This practice is, as is well known, not confined to any particular class of periodicals, for even the most respectable of them eagerly bite at the bait. We doubt whether there can be found to-day, over this country of ours, more than half-a-dozen journals, religious or political, that dare refuse admission into their advertising columns of any quack nostrum that may be offered. On other points they may be orthodox enough; very many will not advertise licentious books, improper places of amusement, and not a few religious papers will go so far as to refuse the announcement of new works of fiction; but at the same time column after column of testimonials of cure by this and that remedy will appear with every issue. The very rarity of the contrary practice will warrant us in alluding in terms of commendation to the *American Agriculturist*, which for some time past has not only refused insertion to quack remedies, but has taken every pains to expose the swindling venders of the same. In the March number of this monthly is the following declaration in point:—

"In reply to many inquiries about a variety of 'doctors,' we say positively, for the fortieth time, that *not one* of the doctors for eyes, ears, private diseases, consumption—and everything else—who advertise themselves, is worthy of a moment's confidence. Write a letter to them, or let them get hold of your case in any way, and it will be 'your money or your life,'—very often *both*."

If every first-class periodical would do the same, what an influence for good could be wielded in the cause of poor credulous humanity! How many thousands of lives would be saved, and how many more would preserve the health not only of body, but of mind! But we cannot expect this; the temptation of money is too great with most of them to be resisted. We see, however, an indication of what can be done when the proper motives are at work, and we cannot do more than hope that other high-toned and influential papers may follow the example. If they cannot go thus far in actually condemning this species of medication, the profession of medicine in the interests of humanity have a right to ask that the editors of such papers will not actually endorse the evil-doers by ill-advised and voluntary commendations. These gentlemen have a responsible duty to perform in this respect as censors of the community. Their opinions on almost every question that comes up for discussion are respected, and they should be accordingly very careful how they express them, and not abuse the trusts which are reposed in them. Their sole object should be to benefit the community by pointing out to them the right paths to pursue. In almost every department of human thought this principle is consistently carried out save in medicine, the discussion of matters pertaining to which is as important as that of any other, not even excepting the national debt, political economy, municipal reform, belligerent rights, etc.

The general voice of the medical profession is in favor of informing the people on medical matters, as far as is consistent with making them the proper judges between falsehood and truth; and if the press will not consent to aid them, there is no reason why any layman connected with it should be always ready to thwart the design by venturing opinions founded on the grossest ignorance. If the general public are in search of the miraculous, there is no good reason why some "wonderful discovery in medicine" should be hatched in the brain of an itemizer to supply the demand, and then palmed off "on the authority of an eminent surgeon."

The same may be said concerning others who hold similar relations to the public, if such believe that So and So's pain-killer is a cure-all, or that the soothing syrup is a boon to poor suffering infants, or that some worm-killer is perfectly safe, or that a balsam is a sovereign remedy for all lung diseases, etc.; let them recollect that in the matter of opinion on such subjects they are out of their depth, and by ventilating the same nothing but harm can come to such as may foolishly trust in their judgment.

The profession are not ashamed of the truth in medicine, but are jealous of the influences which may grow out of the propagation of falsehood. The safest way to give medical facts to the community is to quote them from some medical journal of standing, or entrust them to the discrimination of some medical gentleman who can consistently comment upon them if he deems it necessary. This, we are happy to say, is done with some journals, among which is the one we have previously quoted, which is fortunate enough to have a thoroughly educated physician on its editorial staff.

Reviews and Notices of Books.

THE JOURNAL OF THE GYNÆCOLOGICAL SOCIETY OF BOSTON. Edited by W. LEWIS, H. R. STORER, and G. H. BIXBY. Vol I. July to December, 1869. Boston: James Campbell, 18 Tremont street.

THIS journal is issued monthly, and is a faithful record of the views, discussions, and experiences of the gentlemen composing the Gynæcological Society of Boston. Many of these opinions are of much practical interest to the profession at large. Many of the cases and operations reported are highly instructive, and the treatment, both surgical and medical, is often different from that to which the profession are accustomed. It is generally rather heroic, but it may perhaps be questioned whether it is better or worse for the patient than the treatment commonly adopted. The members of the Society claim that they are progressive, and they sometimes claim it rather loudly, so that we are not surprised to find some peculiarities in their means of cure. There is one therapeutic measure suggested, however, the very mention of which must occasion both surprise and disgust. We allude to the remarks made by Dr. Field regarding a case of erotomania, presented by Dr. Storer (July No.), to the effect that sexual hard labor at a house of prostitution might prove the patient's salvation. To the same unhappy patient Dr. Storer had "jokingly" said "he believed he should have to sew up her vulva closely." Surely a decent regard for the proprieties of life and language is due even from the most progressive gynæcologists.

We have also some little fault to find with the egotistic tone of the journal. It may have been in good taste for the various editors to parade their respective biographies before the public at the outset of their labors, but for our own part we should rather know them by their fruits than by their biographic leaves. There is too much fondness shown for personalities and for personal controversies of no interest whatever to the profession. We hope that time will remedy these and all other defects, for the journal contains a large amount of valuable original matter, and we cannot but recognize it as a bold, energetic, and prosperous contemporary.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MARCH 9, 1870.

DR. JOSEPH C. HUTCHISON, PRESIDENT, in the Chair.

THE Committee on Microscopy reported Dr. Sayre's cases of supposed cancer of the abdominal organs to be tuberculous in character, Dr. Finnell's case of uterine tumor to be polypoid, and Dr. Smith's specimens of infant lung to be catarrhal lobular pneumonia.

COMPLETE FATTY DEGENERATION OF MUSCLES OF CALF OF LEG.

DR. MASON exhibited a specimen of complete fatty degeneration of the muscles of the calf, removed from a middle-aged dissecting-room subject, supposed to have had paraplegia for a long time. There was also found Pott's disease of the three last dorsal.

SIMPLE HYPERTROPHY OF HEART—GASTRITIS—DEATH FROM INEBRIETY.

DR. FINNELL presented the heart, kidneys, and a portion of the liver, removed from the body of a physician of this city. The gentleman, in consequence of the loss of a considerable amount of money in a mining speculation, became so despondent that he fell into habits of intoxication. His favorite beverage was gin, of which he took very large quantities. He finally suffered from a very severe attack of *delirium tremens*, during the recovery from which he was seized with formidable gastritis. The stomach being incapable of tolerating any food, he was urged by his medical friends to fast for a few days, but to such little purpose, that the moment they would leave him he would send for the most indigestible dishes, and devour them with a maniacal avidity. The gastric irritation was constantly increased, when he finally died with asthenia. At the autopsy, the heart was found to be the seat of simple hypertrophy, the liver was in a state of fatty degeneration, and the kidneys were granular.

A second specimen by Dr. Finnell was fragments of gall-stone, presented on behalf of Dr. Fanning, of Tarrytown, removed from a lady, seventy-one years of age, who died of cholæmia.

THE PLACENTAL DECIDUA.

A third specimen was a uterus, taken from the body of a woman thirty-eight years of age. She was the mother of several children, and had an accidental abortion in the sixth month of utero-gestation. As she had been attended by an irregular practitioner, and as there had been some suspicions of foul play, the case was turned over to the coroner. It was evident, however, on examination, that there was nothing wrong in the

case, but that immediately after the delivery she had been seized with uterine phlebitis, of which she died. A plentiful supply of pus was found on section in the uterine veins. The internal surface of the uterus presented a mamillated appearance, resembling an adherent placenta.

Dr. Rogers thought that such a condition was due to the presence of the placental decidua.

COMPOUND COMPLICATED FRACTURE OF SKULL WITHOUT SYMPTOMS.

Dr. Sayre exhibited some fragments of bone removed by operation from the cranium of an Irishman, aged thirty-six, who had been injured by an explosion of nitro-glycerine in Melrose, Westchester County. He found the patient, shortly after the accident, perfectly conscious, pupils natural, and, aside from a slow pulse (sixty), there was nothing peculiar about his general symptoms. Behind the right parietal bos were a number of small scalp-wounds, only separated from each other by small bridles of tissue. These latter were divided with a scalpel, when it was discovered that a considerable portion of the parietal bone posterior to the bos was depressed. This was elevated, and afterwards found composed of a large number of splinters, which were duly removed. Immediately underneath, on the surface of the brain, was a large clot of blood, three or four ounces in quantity, evidently from the middle meningeal artery, which, being scooped out with the spoon, allowed the brain to come up to its normal position. Before the doctor left the house, the patient was by the stove, in an adjoining room, smoking his pipe. At last accounts the patient was doing well, not having, save perhaps the slow pulse, an unpleasant symptom. In connection with this case, he referred to one mentioned by Dr. Parker in his lectures, in which a man had received an extensive depressed fracture of the frontal bone from the kick of a horse, and in which, likewise, no cerebral symptoms showed themselves.

Dr. Hutchison alluded to a somewhat similar case which had come under his observation—that of a boy, who fractured his skull through the whole thickness of the bone, accompanying which was marked depression. The fragment was elevated, and the patient rapidly recovered. In this instance there were no symptoms whatever of depression, or even concussion, notwithstanding considerable blood had been effused.

MULTIPLE TUMORS.—CAN CANCER DISAPPEAR SPONTANEOUSLY?

Dr. Watts presented several portions of the body of a patient with the following history, for which he was indebted to Dr. F. Simrock, who had the patient under observation up to the time of his transfer to the small-pox hospital:—

Peter Ries, aged thirty-three years, a German, a cabinet-maker, applied at the Department for Skin Diseases of the German Dispensary on the 27th of April, 1869, on account of the appearance of several black tumors on different parts of the surface of the body. Some of these little tumors, whose size at that time did not exceed that of a silver sixpence, were seated in the uppermost layers of the cutis and appeared quite black; others were seated in the lower parts of the cutis and subcutaneous cellular tissue, where they could be detected rather by their hard consistency than by their blackish hue, shining through the intact cutis, which was still movable over them. The patient's father died of dropsy, and his mother of cancer of the stomach. The rest of his family are healthy.

The patient stated that he had had, from his earliest childhood, a pigmentary nævus (mole), of the size of a small bean, situated over the angle of the left scapula, which, without any known cause, began to grow larger about two months before, and had then attained the size of an egg. The first melanotic tumors developed right in the vicinity of this mole.

From the first day when he applied for treatment, up to the very last day of his being under observation (a period of about eight months), not a day passed without new tumors being detected, either on the surface of the body or inside the cavities of the mouth, larynx, or ear. From close observation of hundreds of these melanotic tumors in the skin, Dr. Simrock states that they all took their origin from the subcutaneous tissue, and encroached upon the cutis only after they had attained a certain size, until finally they reached the surface of the skin by thinning its elements by pressure from below. As soon as the growths reached the surface they began to undergo marked retrogressive metamorphosis, and shrivelling up and decaying, they gradually disappeared, and left only a black mark as indicating their former presence; and in some cases even this last dark pigmentary discoloration was observed to fade away, leaving the skin only of a somewhat darker hue than in the surrounding parts.

In some instances the surface of the tumors became ulcerated, and a scab formed over them which finally desquamated, leaving only a discolored surface beneath. A few tumors were also observed which showed no pigmentation. About two months after the first came under observation he began to complain of his eyesight, and specially of soreness of the left eye, when the existence of a melanotic tumor of the size of a large pin's head was detected in the inner and upper half of the iris. The ophthalmoscope revealed nothing of importance in the other tissues of the eye, except a high degree of vascular ciliary and retinal irritation, to which the diminution of his visual power in that eye to one-seventh must be ascribed. In a very short time, about fourteen days, the iritic tumor developed to its utmost size—about the diameter of a large pea—and then in about the same length of time it ran through its retrogressive stage, until finally only some extremely slight discoloration of the affected spot could be observed. In direct ratio with the retrogression of the tumor the visual troubles decreased, and when the tumor had entirely disappeared the vision was about normal.

Such was not the course of the disease in the right eye, which at the time it was first examined had vision equal five-sixths. The ophthalmoscope revealed the existence of a morbid process in the deeper parts of this eye, the details of which, however, could not be made out, owing to turbidity of the vitreous humor, and especially to the presence of large floating bodies in the equatorial zone of the corpus vitreum.

A normal field of vision and no increased tension of the globe argued against the probability of a tumor developing in the posterior part of the eye. The choroidal process, unimportant as it was in the commencement, made constant progress, and certainly contributed more toward the total occlusion and adhesion of the pupil, than did the subsequent development of a melanotic growth in the iris of this eye. This growth in the right eye was of about the same size as that in the left, but its appearance was accompanied by a good deal more irritation, in consequence of the serious changes which had already occurred in the eye previous to its development. The vision in this eye became reduced to only quantitative perception of light.

(An examination of the eyes to ascertain the lesions has not yet been made.)

The patient's general condition underwent no marked change for the worse until some large tumors developed

in the tongue, the painful condition of which materially interfered with mastication and deglutition, and this began to tell on his nutrition.

Up to the latter half of October the man continued to work at his trade and had not lost a single day. About that time he became feverish and was admitted to the German Hospital. While there a varioloid eruption appeared, and he was transferred to the Small-pox Hospital, on Blackwell's Island, on December 13th, 1869.

The patient had a mild attack of varioloid, from which he recovered without any untoward symptom, but he failed steadily in strength afterwards. One of the melanotic tumors on the right side of the tongue near its root was very deeply ulcerated, and so painful that it was difficult for him even to swallow. The surface of the body was covered with innumerable black tumors varying in size from that of a small shot to that of a hickory-nut. The small-pox pustules developed upon these tumors as well as in the surrounding healthy skin, and ran the same course in both situations. The skin became of a grayish-yellow color and greasy appearance, and emitted a heavy, sickening odor, entirely different from that produced by small-pox.

Without the development of any special symptoms he gradually failed in strength, and died exhausted on January 13th, 1870.

Dr. Simrock says: "The diagnosis of the character of all these metastatic tumors was based upon the microscopic examination of the primary one, and of several others which were taken out for the purpose. The primary tumor, from the back, proved to be true sarcoma, in the formation of which the fusiform and round cells equally participated. Pigmentary particles I was not able to see in any of the sarcomatous cells. The pigmentary part of the tumor was entirely intercellular, and appeared in the form of irregularly shaped particles and cakes of different tinges, from blood-red to deep black, in the formation of which the extravasated and stagnated blood may have had its part. The other constituents of the tumors (such as the large quantity of fibrous tissues and sudoriparous glands) must be considered as accessory ones, owing to the place of their insertion and their subsequent development through the elements of the skin.

"One small tumor, the size of a bean, was extirpated from the inner side of the left humerus, and showed the same small sarcomatous elements as the primary one, with pigmentary interspersion as the chief characteristic part of its constituents.

"Two particles were removed from tumors which afterwards disappeared almost entirely, leaving only a discoloration of the skin. One of these was from the ear and the other from the eyelid, and in both the same characteristic elements of sarcoma were undoubtedly prevalent.

"If late microscopical examinations corroborate my diagnosis of true sarcoma, then its spontaneous disappearance will prove a precious experience to the ophthalmologist and pathologist. Virchow remarks in his book on tumors 'that up to this time he knows of no well-proved case of sarcoma having spontaneously disappeared.'"

The following is the history of the post-mortem examination made by Dr. Eno, Asst. Curator of Charity Hospital:—

Autopsy 36 hours after death. No rigor mortis. Body below medium size, thin, but not extremely emaciated. Color of skin dark, and upon the face and neck almost olive. The whole surface of the body spotted with black tumors, varying in size from that of a pin's head to that of a half-dollar, generally rounded in form, and projecting about ¼ inch above the surface, smaller upon the neck and face, and largest upon the trunk. Very small tumors also observed upon the conjunctiva: none upon the scalp, and none in or under the nails.

Head.—Black tumors on both surfaces of the dura mater, those on the outer surface following the course of the vessels, also on the falx cerebri. Calvarium covered with pigment in spots corresponding to the tumors on the dura mater.

The arachnoid covering the convexity of the brain thickened and opaque generally along the course of the vessels, and in spots.

Melanotic tumors generally small in the substance of the brain, larger upon the surface, and upon the walls of the lateral ventricles.

Thorax.—Pleuræ, both parietal and visceral, and also the pericardium, studded with small black masses. Heart weighed 14 oz. Walls of left ventricle very thick. External surfaces covered with pigment spots, some projecting, others not. In the substance of the heart the pigment seemed to follow the course of the muscular fibres. The columnæ carneæ, as well as all the internal surface of the organ, were mottled with similar masses, but not the valves nor the aorta or pulmonary artery.

Lungs.—Old adhesions on right side, and lower lobe in first stage of pneumonia. A few small cicatrices at apex of left lung.

Both lungs infiltrated with pigment matter throughout. Mucous surface of larger bronchial tubes contained spots of pigment. Bronchial glands enlarged and black.

The diaphragm contained melanotic tumors on both surfaces and in its substance, as did also the peritonæum, both visceral and parietal, the omentum, the stomach, the intestines, large and small, the pancreas, and the mesenteric glands, which were also enlarged.

The spleen weighed 6 oz., dark in color, and firm.

The liver weighed 3 lbs. 9 oz., dark in color, containing many small tumors, especially near the surface, and in the thin portion. There was one large one in the right lobe, of the size of a walnut, and extending ¾ inch into the substance.

Kidneys.—Left 3 oz. Right 7½ oz. Pelves, especially that of the left, spotted with little black tumors. The substance of the organs, especially the cortical portion, much pigmented. Pyramidal portions comparatively free from deposit.

The internal surface of urethra and bladder studded with small melanotic tumors,—a few also in substance of the corpora cavernosa and prostate gland. Similar tumors were found also in the testicles, and in the tissues of the cord.

The muscles throughout the body, wherever examined (neck, chest, abdomen, back, thigh, lower extremities, &c.), were infiltrated with the same black pigment, which followed to a marked extent the course of the muscular fibres. On making longitudinal section of the femur, black masses were also seen imbedded in the cancellous tissue of the bone.

Dr. Francis Delafield, M.D., has kindly furnished me with the following result of the microscopic examinations of the tumors from various localities, made by himself:—

"In the *Lung* the pigment is in the shape of fine granules, in the walls of the alveoli and bronchi, and in the large round cells ordinarily found adhering to the walls of the alveoli.

"In the *Kidney* the pigment is deposited in granules, and enclosed in small round cells in the stroma, especially in the cortical portion, and follows the vessels in the pyramids.

"In the *Omentum* the pigment is contained in round

and oval cells heaped together. Pigment is also contained in many of the scattered oval cells of the connective tissue.

"In the *Intestines* the pigment is contained in small round cells in the sub-mucous and sub-peritoneal connective tissue.

"In the *Skin* there are small black nodules in the cutis, and irregular masses in the subjacent connective tissue. The pigment is infiltrated in granules, and also contained in round and ovoid cells.

"In the *Muscles* the pigment is infiltrated in granules in the connective tissue, and is also contained in ovoid and fusiform cells.

"In the *Stomach* the pigment forms masses in the mucous membrane, and projecting from its internal surface. The smallest nodules are composed of round cells containing pigment, and situated in the deep layers of the mucous membrane.

"In the *Dura Mater* the pigment forms masses projecting on the internal surface, and also in the membrane itself: here also the pigment is contained in round cells.

"So far as these specimens go, the disease is simple, multiple melanosis."

FATTY LIVER FROM METAMORPHOSIS.

Dr. Robert Newman presented specimens on behalf of Dr. Lewis Smith, taken from the body of an infant six months old, who died four days before. It had a slight diarrhœa for some time, when two weeks before its death the upper and lower extremities became anasarcous. The face was slightly œdematous, but there was no effusion in either the thorax or abdomen. There was also some purpura present, as well as a slight cough. Death was the result of asthenia.

At the autopsy the liver was found unusually large, weighing ten and a half ounces, and intensely fatty. The tissue of this organ under the microscope was found almost entirely devoid of liver-cells, these being only in the proportion of one-eighth of the whole, leading to the conclusion that the disease was due to a metamorphosis of the cells into fatty matter, rather than to a deposit of the material between them, and into their substance. The gall-bladder was filled with healthy bile, showing that there had been no interruption to the secretion. The kidneys and heart were perfectly healthy. The anterior portion of superior lobe of right lung was the seat of a circumscribed pneumonia which accounted for the cough. The inflammation was of the catarrhal variety. The follicles of the colon were somewhat enlarged, and its mucous membrane presented some circumscribed spots of inflammation. Entero-colitis was diagnosticated during life.

INVAGINATION OF INTESTINE IN CAMEL.

Dr. F. Delafield presented a portion of the intestine of a camel, which animal died in the city, the specimen having been presented to Prof. Wood's Museum. The small intestine about its middle was the seat of a complete invagination. Between the peritoneal and muscular coats was a deposit of a thick clot of blood, while there were numerous patches of recent lymph on the peritoneal surface.

IDIOPATHIC CROUPOUS INFLAMMATION OF STOMACH.

Dr. Delafield also exhibited a stomach for which he was indebted to Dr. A. L. Loomis. The following history was taken from the hospital records:—David Adams, 47, Ireland, boiler maker, admitted Jan. 3, 1870. Partly deaf 30 years. Well up to 6 days before death, when he caught cold, got better; 3 days after, another cold, pains over bowels, constipation, cough, white frothy sputa, face flushed, temp. 102½, pulse 120, friction sound over lower part of right lung, tenderness over liver. Jan. 7. Temp. 101, pulse 112, tongue dry, abdomen tympanitic and tender. 3 P.M. Syncope, ½ hour died.

Autopsy.—No lesion found in the thoracic viscera, save a slight effusion in the bronchi. Over the lesser curvature of the stomach, extending from the anterior to the posterior walls, and from near the duodenum to the œsophagus, was a deposit of a thick membranous material. Where this deposit was most extensive the coats of the stomach were thickened, otherwise there was no change in the organ. The deposit was easily detached and minutely examined; was found made up of coagulated fibrine, entangled in which was a moderate amount of lymphoid cells. This layer of coagulated fibrine and cells was closely adherent to the surface of the mucous membrane and dipped down into the mouths of the follicles. Furthermore, there were a number of lymphoid cells in the connective tissue between the follicles, also the same cells with a variable amount of coagulable fibrine in the submucous connective tissue, and the same cells but in small quantities in the muscular coat. The peritoneal coat presented no change. This was then an example of marked croupous inflammation, with a distinct croupous false membrane formed upon the stomach, occurring in a man with a sufficiently complete history to enable us exclude those diseases in which such lesions have been found to exist. As far as he knew to the contrary, this lesion was only a concomitant of exhausting diseases, and had never been described as occurring idiopathically.

HEMORRHAGE AFTER ACUPRESSURE, ETC.

Dr. Hutchison exhibited a portion of artery as forming a part of the history of acupressure. It was removed from a man fifty-four years of age, whose leg had been amputated for compound comminuted fracture. The anterior and posterior tibial arteries were closed by acupressure, the second and fifth methods having been employed. The peroneal artery was closed by torsion. This man was of feeble constitution, and copious suppuration and sloughing occurred in the wound. On the ninth day after the operation profuse secondary hemorrhage took place, which was arrested by the application of the tourniquet, which instrument was kept on for several hours. Subsequently symptoms of pyæmia appeared and death occurred thirty days after the operation.

The specimen illustrated the effects of acupressure thirty days after the application of the needle. The anterior and posterior tibials were closed with plugs,—reddish clots,—which were quite firm but not very adherent to the lining membranes of the vessels. The orifices were closed by lymph, but not so firmly as usual.

He remarked that he was unable to satisfy himself as to the source of the hemorrhage, but was content to present the facts of the case.

The Society then went into Executive Session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 7, 1870.

Dr. George T. Elliot, President, in the Chair.

The President announced the admission to membership of Drs. Morton Folsom, David Coles Carr, and John Dwyer; also the death of Dr. Charles McCaffry, a member of the Society since 1831.

The Report of the Committee on Intelligence was read by Dr. Thompson, and that of the Committee on Diseases by Dr. Raborg.

PROGNOSIS IN CHRONIC DISEASES OF THE HEART.

Dr. Austin Flint, Sen., read an extended paper upon this subject, which will appear in the *New York Medical Journal* for May. In our brief abstract, for which we are indebted to the courtesy of its editor, we shall only indicate a few of the prominent points.

The prognosis in cases of organic disease of the heart becomes a matter of great importance, from the wide-spread belief among the laity, shared also by too many physicians who have inherited the error from a past generation, that all such cases are liable to terminate at any moment in sudden death. Hence the moral effect upon a patient, of informing him that he has heart-disease, unless at the same time we can convince him of the erroneousness of the popular notions upon the subject, may be such as not only to render his life one of constant apprehension, but even materially to shorten it, from the reaction of this state of mind upon the general health.

With our present means of physical diagnosis, heart-lesions can be discriminated with more accuracy than almost any others. But the clear recognition of the lesions in a given case, though indispensable, is yet of itself by no means a sufficient basis for the prognosis, which must be broadly founded, as well, upon the lessons of clinical experience. These have taught us to take into account not only the differing gravity of different lesions (some of them being often nearly innocuous), but also the many and important modifying conditions in the individual cases of the same lesion. Our limits forbid us to follow the paper through its account of these lesions and conditions; of how one lesion may be conservative in preventing the evil effects of another (hypertrophy, for example, compensating for obstructive or regurgitant valvular affections, and *vice versâ*; one valvular affection diminishing the dangers from another, etc.); of how disorders purely functional may be mistakenly attributed to a coincident but comparatively unimportant organic disease, and the means of diagnosis in these often difficult cases; of the great weight to be attached to the existence of predominant dilatation, or of fatty degeneration, in determining the gravity of the prognosis.

A topic dwelt upon at length was the great difference in the tolerance of organic affections manifested by different persons. Many a man with what might appear a grave lesion would go on for years unconscious of the fact, living freely, and engaged in active pursuits, until impelled to relinquish his usual habits from discovery of the disease, or forced to do so from other causes, when he would fall into a rapid decline.

In general terms, heart-diseases, like other chronic maladies, are best tolerated when the functions of the body, exclusive of the diseased organs, are kept in a state of healthful activity. To secure this should therefore be our great object in the management of these cases; and upon a wise management the prognosis will in no small degree depend.

In conclusion, the paper treated exhaustively the subject of the liability to *sudden* death from cardiac affections, showing what conditions involved the greatest liability to this event, and their rarity as compared with the great majority of cases of heart-disease.

Dr. Alfred L. Loomis, after presenting a specimen of Thrombi of the Coronary Arteries,* referred to by Dr. Flint, made the following remarks:—

Mr. President: The subject which has been brought before us this evening necessarily elicits a great diversity of opinion; for as yet there are no fixed clinical and pathological data upon which to rest; each observer and writer on this subject holds opinions of his own, based on his personal observation.

It seems to me the questions to be asked and answered are—First, Does heart disease ever directly cause death? second, If so, is it a frequent cause of death? and, third, Is it ever a cause of sudden death? As an answer to some of these inquiries, permit me to present the results of ninety autopsies (in all of which heart-lesions were found) compiled from the post-mortem register of Bellevue Hospital, by my Junior Assistant, Dr. B. D. Taylor.

A Synopsis of the Record of Autopsies made at Bellevue Hospital since June 1st, 1868, in which Valvular Lesions, Hypertrophy, and Dilatation of the Heart, Lesions of the Coronary Arteries, and Cardiac Thrombi were found—setting forth the suddenness of Death, or otherwise, and its causes.

I. HYPERTROPHY AND DILATATION WITH VALVULAR LESIONS.

Case 1. Hypertrophy and slight dilatation. Mitral valves atheromatous. Death *gradual* from Bright's Disease.

Case 2. Hypertrophy and dilatation of right heart. Dilatation of left cavities. Atheroma of aortic and mitral valves. Death *gradual* from Bright's Disease.

Case 3. Hypertrophy and dilatation, with aortic insufficiency. Death *gradual* from Bright's Disease.

Case 4. Hypertrophy (1 lb. 11 oz.). All cavities dilated. Mitral valve thickened. Tricuspid thickened and insufficient. Death *gradual* from Pericarditis.

Case 5. Hypertrophy and dilatation. Vegetations on aortic valves. Mitral valve thickened and orifice stenosed. Death *gradual* from Uræmia.

Case 6. Hypertrophy and dilatation. Aortic valves thickened and insufficient. Mitral thickened. Death *gradual* from Phthisis.

Case 7. Hypertrophy and dilatation. Aortic valves calcified. Tricuspid atheromatous and orifice stenosed. Death *gradual* from Pneumonia.

Case 8*. *Hypertrophy and dilatation of left ventricle. Vegetations on aortic valves. Thoracic aorta atheromatous. Death* gradual *from Heart-lesion.*

Case 9. *Hypertrophy and dilatation of right heart. Mitral stenosis* (⅜ *in.*). *Death* gradual *from Heart-lesion.*

Case 10. *Hypertrophy and dilatation of right heart and left auricle. Mitral stenosis* (½ *in.*). *Death* gradual *from Heart-lesion.*

Case 11. *Hypertrophy* (1 *lb.* 6 *oz.*). *Dilatation of all cavities. Aortic stenosis and insufficiency. Mitral valve thickened and insufficient. Death* gradual *from Heart-lesion.*

Case 12. *Hypertrophy and dilatation. Mitral valve thickened and orifice stenosed* (½ *in.*). *Death* gradual *from Heart-lesion.*

Case 13. *Hypertrophy and dilatation. Mitral and Tricuspid valves atheromatous and insufficient. Death* gradual *from Heart-lesion.*

Case 14. *Hypertrophy* (1 *lb.* 15 *oz.*). *Dilatation of both ventricles. Mitral and Tricuspid orifices stenosed. Death* sudden *from Heart-lesion.*

Summary.—14 cases:—*7 deaths from Heart-lesion,* 1 of them *sudden.* No sudden deaths from other lesions.

II. HYPERTROPHY WITH VALVULAR OR OTHER LESIONS.

Case 1. Hypertrophy. Aortic and Mitral valves thickened. Death *gradual* from Bright's Disease.

* For description and history, see Report of Pathological Society in last number of Record, pp. 40, 41.

* Where death resulted from heart-lesions the records are in Italics.

Case 2. Hypertrophy. Aortic valves thinned. Aorta atheromatous. Death *gradual* from Bright's Disease.

Case 3. Hypertrophy left ventricle. Aortic valves fenestrated. Death *gradual* from Acute Meningitis.

Case 4. Hypertrophy. Aortic valves and Aorta calcified. Death *sudden* from Uræmic Convulsion.

Case 5. *Hypertrophy. Aortic valves thick and rigid. Mitral stenosis from vegetations. Death* gradual *from Heart-lesion.*

Case 6. *Hypertrophy. Aortic and Mitral valves atheromatous. Death* gradual *from Heart-lesion.*

Case 7. *Hypertrophy. Aortic and Mitral valves atheromatous. Aorta and Pulmonary artery dilated. Death* gradual *from Heart-lesion.*

Case 8. *Hypertrophy. Aortic and Mitral valves and Arch of Aorta calcified. Death* gradual *from Heart-lesion.*

Case 9. *Aortic and Mitral valves atheromatous, and latter orifice stenosed. Death* gradual *from the Heart-lesion.*

Case 10. *Hypertrophy. Aortic valves calcified and stenosis of the orifice. Death* gradual *from Heart-lesion.*

Case 11. *Hypertrophy. Aortic valves calcified, and stenosis of orifice. Death* sudden *by Syncope.*

Case 12. *Hypertrophy. Mitral valve thickened and rough, free regurgitation. Death* sudden *from Heart-lesion.*

Case 13. *Hypertrophy. Mitral and Tricuspid valves atheromatous. Death* sudden *from Heart-lesion.*

Case 14. *Hypertrophy. Aortic and Mitral valves and whole Aorta atheromatous. Death* sudden *from Heart-lesion.*

Case 15. *Hypertrophy. Mitral and Pulmonic valves rigid. Death* sudden *from Heart-lesion.*

Summary.—15 cases:—11 *deaths from Heart-lesion*, 5 of them *sudden*. 1 *sudden* death from Uræmic Convulsion.

III. DILATATION WITH VALVULAR OR OTHER LESIONS.

Case 1. Dilatation of right ventricle. Mitral valve insufficient. Death *gradual* from Bright's Disease.

Case 2. Dilatation of all cavities. Aortic valves thickened and insufficient. Mitral same, and nearly all the chordæ tendineæ ruptured. Death *sudden* from Uræmic Convulsion.

Case 3. *Dilatation of right heart. Mitral valve thickened and orifice stenosed (½ in.). Tricuspid valve thickened and rough. Death* gradual *from Heart-lesion.*

Case 4. *Same lesions and termination as in No.* 3.

Case 5. *Dilatation of both auricles (especially left). Aortic and Mitral valves thickened, and stenosis of latter orifice. Death* sudden *from Heart-lesion.*

Case 6. *Dilatation. Aortic and Mitral valves thickened and covered with vegetations; former insufficient. Tricuspid covered with vegetations. Death* sudden *from Heart-lesion.*

Summary.—6 cases:—4 *deaths from heart-lesion*, 2 of them *sudden*. 1 *sudden* death from Uræmic Convulsion.

IV. VALVULAR LESIONS.

(*a.*) *Aortic, Mitral, and Tricuspid.*

Case 1. Aortic, Mitral, and Tricuspid valves thickened. Death *gradual* from Bright's Disease.

Case 2. Aortic and Mitral valves calcified. Tricuspid malformed and fenestrated. Death *gradual* from Gangrene of Lung.

(*b.*) *Aortic and Pulmonic.*

Case 3. Aortic and Pulmonic valves fenestrated. Death *gradual* from Phthisis.

Case 4. Aortic and Pulmonic valves fenestrated. Death *gradual* from Phthisis.

Case 5. Aortic and Pulmonic valves fenestrated. Death *gradual* from Gangrene of Lung.

(*c.*) *Aortic and Mitral.*

Case 6. Aortic and Mitral valves calcified. Death *gradual* from Bright's Disease.

Case 7. Aortic and Mitral valves calcified. Death *gradual* from Phthisis.

Case 8. Aortic and Mitral valves calcified. Death *gradual* from Phthisis.

Case 9. Aortic and Mitral valves calcified. Death *gradual* from Pneumonia.

Case 10. Aortic and Mitral valves calcified. Death *gradual* from Œdema Glottidis.

Case 11. Aortic valves covered with vegetations. Mitral valve insufficient. Death *gradual* from Bright's Disease.

Case 12. Aortic valves thick and fenestrated. Mitral valve covered with vegetations. Death *gradual* from Subacute Meningitis.

Case 13. Aortic and Mitral valves calcified. Death *gradual* from Delirium Tremens.

Case 14. Aortic and Mitral valves thickened and covered with vegetations. Death *gradual* from Apoplexy.

Case 15. Aortic and Mitral valves calcified. Death *sudden* from Croupous Laryngitis.

Case 16. Aortic valves covered with vegetations. Mitral valve insufficient. Death *sudden* from Uræmic Convulsion.

Case 17. Aortic valves and Aorta calcified. Mitral insufficient. Death *sudden* from Apoplexy.

Case 18. *Aortic and Mitral valves calcified, and fenestration of the former. Whole Aorta calcified. Death* gradual *from Heart-lesion.*

Case 19. *Aortic valves calcified. Mitral orifice stenosed. Death* gradual *from Heart-lesion.*

(*d.*) *Aortic.*

Case 20. Aortic valves thickened. Death *gradual* from Cholæmia.

Case 21. Aortic valves and Aorta atheromatous. Death *gradual* from Cerebral Softening.

Case 22. Aortic valves calcified. Death *gradual* from Phthisis.

Case 23. Aortic valves calcified. Death *gradual* from Phthisis.

Case 24. Aortic valves calcified and fenestrated. Death *gradual* from Phthisis.

Case 25. Aortic valves calcified. Death *gradual* from Bright's Disease.

Case 26. Aortic valves calcified. Death *gradual* from Bright's Disease.

Case 27. Aortic valves calcified. Death *gradual* from Bright's Disease.

Case 28. Aortic valves calcified. Death *gradual* from Pneumonia.

Case 29. Aortic valves and Aorta calcified. Death *gradual* from Pneumonia.

Case 30. Aortic valves calcified. Death *gradual* from Gangrene of Lung.

Case 31. Aortic valves calcified. Death *gradual* from Pyæmia.

Case 32. Aortic valves calcified. Death *gradual* from Cerebro-Spinal Meningitis.

Case 33. Aortic valves covered with vegetations. Death *sudden* from firm and short old Pericardiac Adhesions.

Case 34. Aortic valves perfectly rigid. Death *sudden* from Cerebral Apoplexy.

(*e.*) *Mitral.*

Case 35. Mitral valve calcified. Death *gradual* from Puerperal Peritonitis.

Case 36. Mitral valve calcified. Death *gradual* from Pneumonia.

Case 37. Mitral valve calcified. Death *gradual* from Pneumonia.

Case 38. Mitral valve calcified. Death *gradual* from Pneumonia.

Case 39. Mitral valve calcified. Death *gradual* from Phthisis.

Case 40. Mitral valve calcified. Death *gradual* from Phthisis.

Case 41. Mitral valve calcified. Death *gradual* from Phthisis.

Case 42. Mitral valve calcified. Death *gradual* from Phthisis.

Case 43. Mitral valve calcified. Death *gradual* from Septicæmia.

Case 44. Mitral valve calcified. Death *gradual* from Pyæmia.

Case 45. Mitral valve calcified and stenosed. Death *sudden* from Apoplexy.

Case 46. Mitral valve calcified. Death *sudden* from Apoplexy.

Summary.—46 cases:—2 *deaths from Heart-Lesion*, neither of them sudden. 7 deaths *sudden:* 4 from Cerebral Apoplexy, 1 from Uræmic Convulsions, 1 from Croupous Laryngitis, and 1 from old Pericardiac Adhesions.

V. LESIONS OF CORONARY ARTERIES.

Case 1. Coronary Arteries ossified. Aortic and Mitral valves calcified. Died comatose from inflammation of the lining membrane of the ventricles of the brain and nervous tissue adjacent.

Case 2. Coronary Arteries calcified at their commencement. Aortic and Mitral valves calcified. Death *gradual* from Gangrene of Lung.

Case 3. *Coronary Arteries completely plugged by Thrombi. Death* sudden *from Heart-lesion.*

VI. THROMBI OF THE HEART.

Case 1. Thrombus size of a cubic inch in the left ventricle, which is hypertrophied. Death *gradual* from Cerebral Softening.

Case 2. Several Thrombi the size of hickory-nuts in the left ventricle, which is hypertrophied, and the aortic valves thickened and fenestrated. Death *gradual* from Acute Nephritis.

Case 3. A Thrombus the size of a pigeon's egg in the left ventricle. Vegetations on the Mitral valve. Death *gradual* from Cerebral Softening.

Case 4. Large Thrombus in right auricle. Death *gradual* from Invagination of the Ileum.

Case 5. Thrombus of right auricle. Mitral valve calcified. Death *gradual* from Pneumonia.

Case 6. *Large Thrombus of the right ventricle. Death* sudden *from the Heart-lesion.*

DR. LOOMIS resumed:—

From this report it will be seen that valvular disease, cardiac hypertrophy, and dilatation were present in 14 cases. Of this number heart-lesions were the cause of death in 7; death was sudden in 1, and was caused by stenosis of the mitral and tricuspid orifices.

In 15 cases valvular lesions with cardiac hypertrophy were present, in 11 of which the heart-lesions were the cause of death; in 5 of these death was sudden, and the valvular lesions were aortic in one, mitral in another, aortic and mitral in another, mitral and tricuspid in another, and mitral and pulmonic in another.

In 6 cases valvular lesions with cardiac dilatation were present. In 4 of these the heart lesions were the cause of death; 2 died suddenly, in 1 the valvular lesions were mitral stenosis and aortic thickening, in the other the aortic, mitral, and tricuspid valves were all diseased.

In 46 cases valvular lesions were present without cardiac hypertrophy or dilatation. In only 2 of these were heart-lesions the cause of death, in neither of which was death sudden. Lesions of the coronary arteries were present in 3 cases; in 1 death was sudden. Thrombus of the heart was present in 6 cases, death sudden in 1.

From this report it will also be seen that the number of deaths due directly to heart-lesions was 26. In 19 cases death was sudden; number of sudden deaths due to heart-lesions, 10; number of gradual deaths due to heart-lesions, 16; number of deaths not due to heart-lesions, 64. Of the 9 sudden deaths not due to heart-lesion, 4 were from cerebral apoplexy, 4 from uræmic convulsions, and 1 from croupous laryngitis.

The physical evidences of heart disease are mainly abnormal sounds and impulses which may accompany a cardiac pulsation. In other words, cardiac murmurs are all-important in the diagnosis of cardiac affections. Still, any one who carefully studies heart-murmurs soon comes to the conclusion that it is not the loudest or roughest murmur that is most significant or dangerous; the mere fact that a murmur is present in a given case tells very little of its true nature. For some time I have regarded those cardiac murmurs which occur independent of other appreciable cardiac changes as comparatively of slight importance; and I am convinced that valvular lesions developed during the period of the growth of the body are much sooner fatal than those established for the first time at a later period of life.

The records which I have presented give evidence that cardiac murmurs, unless complicated with cardiac hypertrophy or dilatation, rarely necessitate a bad prognosis. Dr. Gairdner states, in his Clinical Medicine, that he has a patient with an extensive mitral regurgitation which has existed for thirty years, and as yet shows no tendency to shorten life.

I have a patient, sixty years of age, with extensive aortic regurgitation, who has been under my observation eight years, during which time he has had three attacks of pneumonia; yet to-day he apparently has as good a tenure of life as at any time since I have known him. There are no appreciable signs of dilatation in his case.

The results of my own clinical and pathological observations lead me to the opinion that so long as cardiac murmurs are not complicated by cardiac hypertrophy and dilatation, with the attending loss of rhythm in the heart's action, our prognosis as regards time is good; but so soon as the signs of considerable dilatation or hypertrophy are present, a great variety of complications are constantly liable to occur, and the heart-disease itself may terminate the life of the individual.

As Dr. Flint has already stated, aortic regurgitation is usually regarded as the most dangerous form of valvular lesion. Of late, however, it has seemed to me that mitral stenosis is equally dangerous. These post-mortem records seem to sustain this opinion. Permit me to name a case in point:—A female, about 30 years of age, a few weeks ago consulted a physician, having walked about one mile and a half to his office. The physician recognized stenosis of the mitral orifice and intense pulmonary congestion. He ordered her to be conveyed to Bellevue Hospital; she, however, walked there, a distance of nearly two miles, and died in about fifteen minutes after reaching the hospital. The only heart-lesion found at the autopsy was mitral

stenosis (one finger could hardly be forced through the mitral orifice) and great dilatation of the left auricle. She evidently died of acute pulmonary congestion and œdema, caused by the cardiac lesion and developed by her long walk.

This variety of valvular lesion, it seems to me, has not received sufficient attention. To Dr. Flint is due the credit of first calling attention to it in this city.

(To be continued.)

Correspondence.

RELAPSING FEVER IN NEW YORK IN 1847–8.

NOTE REGARDING DR DUBOIS'S CASES OF OPHTHALMIA AFTER FEVER.

To the Editor of the Medical Record.

Sir—As an appendix to the lecture on Relapsing Fever, please publish the following note:—My valued friend and medical college classmate, Dr. A. Dubois, is quoted abroad as reporting certain cases of relapsing fever occurring in this country. Dr. Dubois published in the Transactions of the Am. Med. Association, vol. i. p. 373 and onward, the best paper that has yet been written on the treatment of "Ophthalmitis postfebrilis." His paper was founded on twenty-nine cases observed at the New York Eye and Ear Infirmary in 1847–8. During those years typhus was a sweeping epidemic in this city. It was at that time that Dr. Metcalfe, Dr. A. G. Elliot, the late Dr. Gilman, and myself, two and two alternately, for many months, had charge of and visited daily two hundred and fifty patients suffering from that disease. If there had been at that time an epidemic of relapsing fever, it could not have escaped our notice. It was then that we saw well-marked instances of relapse in typhus. So did Dr. Swett at the New York Hospital. As quoted by Dr. Dubois, he says: "In some cases convalescence had advanced regularly for a week, or even two weeks, when all the symptoms of the fever returned, even to the eruption over the body." But this was a disease attended by "an abundant rose-colored rash," which appeared over the whole body. This rash, "so striking and characteristic, appeared abundantly on the trunk, sometimes on the limbs. In some cases livid spots were noticed." The condition of the tongue, brain, and the nervous symptoms did not materially differ from those noticed in the fever of former years [the typhoid affection of Louis is the indigenous fever of New York; typhus has thus far always been imported], except that the prostration was more rapid and marked in many cases. There was diarrhœa without pain or tympanitis frequently; *duration, two to three weeks;* convalescence rapid. These were some of the features of the disease, the relapsing of which Dr. Dubois found to be followed sometimes by ophthalmitis. This is not relapsing fever. There was no constant lesion—no enlargement of the spleen. "Occasionally the glands of Peyer have been affected, and generally they have been noticed as being more distinct than usual, without, however, being properly diseased."

Dr. Dubois quotes from European authors the description of what is now called relapsing fever, and points out the resemblances that he finds between the fever in the New York Hospital and the foreign epidemics, and there stops; he says not a word about *identity*. In truth Dr. Swett's description gives prominence to symptoms which relapsing fever has not; gives a duration to the disease, which, though short for typhus or typhoid, is much too long for relapsing fever; and then he makes no allusion to the characteristic repeated crisis, and none to muscular pains. The fever described by Dr. Swett came from the same sources as that which filled Bellevue, was the same epidemic, and, as I can testify from personal examination in repeated visits, was substantially the same disease. I therefore had never thought of that paper as announcing the existence of relapsing fever in this country. But, on reviewing now the eight cases published as illustrations of his subject, I find there are four that could hardly have been anything else than relapsing fever. Of two it is stated that they had just arrived in the country, and of the other two no record is made relating to this point. Of the other four, three had no relapse; and of one the only statement is, "had fever in July, which was followed by relapse;" so that the character of the fourth cannot now be determined with certainty.

But here a point should be raised. In his second case the man "was ill between five and six weeks without any remission." He had come from the country and took the prevailing fever, typhus. Again, his fifth case, she "had fever in Aug.; she did not fully recover her health till the latter part of October;" relapse is not mentioned. Here then are two cases of typhus fever followed by "Ophthalmitis postfebrilis." The third may have been of the same character, or it may have been relapsing fever without the relapse. This is the record: "Wm. Brady, aged 17, admitted March 31st, 1848, had fever on his voyage from Liverpool, in Dec. last; ill ten days; no relapse." In children typhus often runs its course in nine or ten days, and occasionally in persons at 17. Then, on the other hand, we have seen that the first stage of relapsing fever may last ten days, and we have learned that the relapse is not absolutely constant. Still the fact remains that, so far as we can learn from the specimen-cases, Dr. Dubois had at least two instances in eight of his twenty-nine ophthalmias in which the inflammation followed typhus fever. *Ophthalmitis postfebrilis can occur, then, after typhus, as well as after relapsing fever.* In 1847 and 1848, the years in which Dr. Dubois recorded his cases, the deaths in New York from fever, almost wholly typhus, though reported to the Registrar under various names, exceeded 1,800 and 1,200 respectively. Those 3,000 deaths represent about 18,000 cases and indicate about 15,000 recoveries. It is easy, therefore, to understand how this unusual prevalence of typhus may have produced an unusual number of cases of ophthalmitis postfebrilis.

But, after all, as I have said, it is pretty clear that Dr. Dubois did see ophthalmia that followed relapsing fever in 1847–8, in at least four cases, the fever occurring either at Quarantine or in the city. But this was not the fever Dr. Swett describes, nor the fever we treated at Bellevue, nor that generally prevalent in the city. It may, therefore, be said that relapsing fever was not, then, epidemic, and there is no evidence that it has ever been epidemic in this country till the present time.

But I will transcribe the report of these four cases so far as relates to the ante-ophthalmic fever:

"*Mary Gall*, aged 13 years, landed at Quarantine on the 1st of June, 1847. Many of her fellow passengers were sick with fever on the voyage. About the middle of June she was taken ill of the same disease; was confined to her bed for twelve days; relapsed after two days. Second attack continued for ten days."

"*Stephen Stanley*, aged 26, was ill of fever at the Quarantine in November, 1847; confined to his bed for ten days; after a convalescence of four days had a relapse; in five weeks from the first attack was perfectly well."

"*Margaret Orpen*, aged 25, taken with fever on the 25th of December; was confined to her bed for a fort-

night; in three days had a relapse, was ill for three days."

"*James Wilson*, aged 35, was taken ill with fever Jan. 14, 1848; convalescent in one week; four days after had a relapse."

In one of Dr. Dubois' cases a *second relapse* was reported.

In these cases the first fever was of short duration, and in two of them relapse occurred on the *fourteenth* day. In the others the relapse was on or near the seventeenth and eleventh days respectively. These were cases of relapsing fever.

The fact that, so far as noticed in this country, this disease has spread only through infection, and the observation of Dr. Harris, that the period of incubation may be fifteen days, associated with the statement of Mary Gall above quoted, render it highly probable that relapsing fever was brought to this city by emigrants on the first of June, 1847.

Again, in November of the same year, it appeared in a person just arrived from Europe. It is to be assumed that his was not the only case in, or from, the ship in which he arrived. It is probable, then, that the disease was twice imported in 1847, and perhaps a third time in December. The extent to which it prevailed, whether it appeared in any except persons newly arrived, we have, probably, lost the means of ascertaining, unless Dr. Dubois' notes can give us further information. Regarding Margaret Orpen and James Wilson, if they were not emigrants, their cases would show some spread of the disease in the city.

A. CLARK.

CORRECTIONS.—The statements made in the last four paragraphs in the second part of my lecture, published March 15, including a tabular exhibition of the symptoms in 103 cases, dated February 15, were sent to the printer as a *post-scriptum* note. They appear as a part of a lecture delivered February 7. The Dr. Moon of those paragaphs is really Dr. Moore.

A. C.

Medical Items and News.

THE BELLEVUE HOSPITAL MEDICAL COLLEGE held its Eighth Annual Commencement at the Academy of Music, February 26th, when degrees were conferred upon 140 students. The address to the graduates was delivered by Rev. Dr. E. H. Chapin, and the Valedictory by Dr. Samuel M. Tucker. Music by Theodore Thomas. The O. A. E. Society of this college celebrated its sixth anniversary three days previous. The President of the society, Dr. Edw. C. Harwood, delivered an address; Prof. Geo. T. Elliot gave a discourse upon *Medical Science at the Present Time*. Regular toasts were responded to by Professors James R. Wood, Henry D. Noyes, and Lewis A. Sayre, and by Drs. Thos. J. Earle and J. W. McWhinnie, of the graduating class. Music by Grafulla's band, and the O. A. E. Glee Club.

COLLEGE OF PHYSICIANS AND SURGEONS.—The Sixty-third commencement of this college was held at Steinway Hall, March 2d. Seventy-four graduates received diplomas at the hands of the venerable President, Dr. Delafield. The two Faculty Prizes were awarded to Dr. Allan McLane Hamilton, for a thesis upon "Galvano-Puncture Applied to the Cure of Aneurisms," and Dr. J. Freeman Atwood for a thesis upon "Bromide of Potassium." Dr. Hamilton also obtained the Harsen Prize for the best Clinical Report of the New York Hospital instructions. The Stevens' Triennial Prize was given to Dr. L. D. Bulkley, for a thesis upon "Thermometry in Disease." The Alumni Prizes were received by Drs. Andrew H. Smith and Albert H. Buck, both of this city, for their respective theses on "Oxygen as a Remedy in Disease," and on "The Mechanism of the Ossicles of the Ear." Honorable mention was made of the thesis of Dr. J. D. Featherstonehaugh, on "Mechanics of the Spinal Cord," of Dr. S. B. St. John, on "The Crystalline Lens," of Dr. John V. Morgan, on "Chemical Diagnosis," of Dr. Willard Parker, Jr., on "The Great Sympathetic Nerve," and of Dr. John Green Curtis, on "A Point in the Mechanics of the Foot." The address was given by Rev. Francis Vinton, D.D., and the Valedictory by Dr. D. Brainerd Hunt. The meeting of the Alumni Association took place March 1st, when Dr. W. C. Roberts delivered the address, and the prize committee made its report as above.

WESTERN DISPENSARY FOR WOMEN AND CHILDREN.—This young dispensary, located at 242 Ninth Avenue, sends us its first annual report. Opened in March of last year, in a district sadly deficient in dispensary accommodation, it had, up to the 31st of December, given medical aid to 1279 patients, of whom 692 were adults, and 587 children. To 40 of these patients 217 visits were made at their homes. The Attending Physician is Dr. Mary E. Greene, whose energy did much towards securing the establishment of this charity. The Consulting Board consists of Drs. Jacobi, Reynolds, Leaming, F. Swift, C. C. Terry, B. Howard, S. B. Ward, and Piffard.

THE NEW YORK ORTHOPÆDIC DISPENSARY, 1299 Broadway, incorporated May 1, 1868, presents its second annual report. Its Surgical Board is thus organized: *Surgeons*, Drs. C. F. Taylor and W. E. Vermilye; *Assistant Surgeons*, Drs. Thos. M. L. Chrystie and David C. Carr; *Consulting Surgeons*, Drs. Willard Parker, W. H. Van Buren, C. R. Agnew, J. T. Metcalfe, and E. Krackowizer. Of 189 new applicants at the Dispensary for the past year, 97 were received. The whole number of cases remaining under treatment Jan. 1st was 213. During the year 175 visits were made at patients' residences. The results of treatment are illustrated in the report by accounts of a number of interesting cases.

THE BUFFALO MEDICAL COLLEGE.—The Commencement exercises of the Buffalo Medical College were held February 22d, and the Council conferred the *Degree of Doctor in Medicine* upon 41 graduates.

ALBANY MEDICAL COLLEGE.—Twenty-eight students received the degree of Doctor in Medicine from Albany Medical College, on the 23d of December last.

THREE CASES OF BRONCHOCELE.—Prof. W. Warren Greene (*Boston Med. & Surg. Journal*) has had three successful cases of removal of bronchocele. In the last case the bronchocele was double and of immense size.

THE COMMENCEMENT OF THE JEFFERSON MED. COLLEGE, PHILA.—One hundred and sixty-two graduates received their diplomas at the Jefferson Medical College on Saturday, March 12th.

NATIONAL CONVENTION FOR REVISING PHARMACOPŒIA.—In compliance with a resolution of the National Convention for revising the Pharmacopœia, directing that the names of the delegates announced to the President of the Convention as having been appointed to attend the Convention to meet on the first Wednesday of May next, at Washington, be made public in the newspapers and medical journals in March, the following names of delegates are now published, with

the date at which their appointment was made known to the President in the order of their announcement:

May 27, 1869, *St. Louis Medical College*, A. Litton, M.D.; J. S. B. Alleyne, M.D.

June 6, 1869, *Maryland College of Pharmacy*, Wm. G. Thompson, I. Faris Moore, Louis Dohme.

June 6, 1869, *Missouri Medical College*, Chas. O. Curtman, M.D.

June 25, 1869, *St. Louis College of Pharmacy*, O. F. Potter, M.D.; Hubert Primm, M.D.; Eugene L. Masott.

June 25, 1869, *Chicago College of Pharmacy*, Albert E. Ebert, Henry Biroth, C. Lewis Diehle.

Alternates, Jas. W. Mill; F. Mahle, M.D.; Louis Strihl.

August 9, 1869, *Jefferson Medical College*, John B. Biddle, M.D.; B. Howard Rand, M.D.

December 9, 1869, *Medical Society of District of Columbia*, Thos. Antisell, M.D.; C. H. Liebermann, M.D.; B. F. Craig, M.D.

January 11, 1870, *Medical College of Virginia*, J. S. Willford, M. D.; R. S. J. Peebles, M.D.

January 20, *Massachusetts College of Pharmacy*, Geo. F. H. Markoe, Thos. Dolliber.

February 1, 1870, *Medical Society of the State of New York*, Caleb Green, M.D.; Wm. Manlius Smith, M. D., Ewd. R. Squibb, M.D.

Feb. 3, 1870, *College of Physicians of Philadelphia*, George B. Wood, M.D.; Robert Bridges, M.D.; H. C. Wood, M.D.

Feb. 15, 1870, *College of Pharmacy of New York*, Wm. Hegeman, Wm. Neirgard, P. W. Bedford.

Alternates, Theobald Frohwein, Augustus H. Weismann, Geo. C. Close.

Feb. 16, 1870, *National Medical College (Medical Department of Columbia College, Washington)*, Geo. W. Dore. M.D.; Jno. C. Riley, M.D.

March 10, 1870, *Medical Department of the University of Pennsylvania*, Jos. E. Carson, M. D.; Robert E. Rogers, M.D.

March 17, *Philadelphia College of Pharmacy*, Wm. Procter, Jr., Jno. M. Maisch, Alfred B. Taylor.

The following letter has been received by the President offering the use of the halls for the meeting and subsequent sittings of the Convention.

1407 New York Avenue,
Washington, D.C., Feb. 16, 1870.

Prof. Geo. B. Wood, M.D.

My Dear Doctor—It affords me pleasure to inform you that at a recent meeting of the Faculty of the National Medical College (Med. Dept. of Columbia College) the following resolution was unanimously adopted.

Resolved, That the Dean be instructed to tender to Prof. Geo. B. Wood, the President of the Convention to revise the Pharmacopœia held in 1860, the College buildings for the meeting to be held in May, 1870, and to make the necessary arrangements therefor.

The building is centrally located, in the vicinity of the principal hotels, and is well suited for the purpose.

Respectfully your obedient servant,

Jno. C. Riley,
Dean of Faculty of Columbia College.

Cases of Relapsing Fever at Bellevue Hospital.—Thomas J. Moore, M.D., House Physician to Bellevue Hospital (*N. Y. Med. Journal*), records 103 cases of relapsing fever occurring at this hospital and in the Fever Pavilion from Nov. 14, 1869 to Feb. 16, 1870. Two cases were fatal—one from suppression of urine, the other from the fever.

Dr. H. L. Hodge, Jr., has been appointed Demonstrator of Anatomy in the University of Pennsylvania, vice Dr. D. H. Agnew, resigned.

A new full chair has been created in the Med. Dept. of the University of Pennsylvania, to be entitled Professorship of Clinical and Operative Surgery, and Dr. D. Hayes Agnew, late Demonstrator of Anatomy, will be invited to fill it.

Empyema Treated by Drainage Tubes.—Dr. Paley, of Peterborough, has treated two children, both of the age of ten, for empyema, by first making an opening into the chest by means of a trocar evacuating the pus, and then inserting an india-rubber tube, such as is used in feeding bottles, about two feet and a half long, and with a few openings cut into it with a pair of scissors at the end to be left in the chest, for about six inches into the chest through the canula. The tube was secured to two pieces of plaster above and below the opening by means of silk threads, and was kept in six days. The children both made good recoveries.

Chorea by Ether Spray.—M. Perroud, Physician of the Hôtel Dieu of Lyons, has just applied, with much success, the ether spray to the spine of a girl of fifteen, suffering from chorea. Eleven sittings, at each of which between two and three ounces were used with Richardson's apparatus, were followed by complete cure. A second just as successful case occurred under the care of Dr. Meynet, also at Lyons, the patient being a lad of eighteen.

An Attack of Catalepsy of Fifty-four Days.—The *Allg. Med. Zeit.* of Berlin (No. 101, 1869) quotes from the *Presse Méd. Belge* the case of a girl aged twenty, who had suffered in various ways at the catamenial periods. In December, 1868, she threw herself into a river on being taken into custody for some crime. Upon this she was seized with convulsions, and could neither speak nor swallow; a cataleptic state soon followed, and lasted eight weeks. The eyes remained sometimes opened for two or three hours without the lids once moving, and the temperature sank so low that at one time she was thought to be dead. She was eventually roused and did well. The urine flowed involuntarily; but we are not told anything about other evacuations, or about food or sleep. These cases are always unsatisfactory, as (especially in this case) doubts may be entertained respecting the genuineness of the affection.

Movable Kidneys.—Dr. William Roberts, of Manchester, has brought before the Manchester Medical Society five cases of movable kidneys. In four of them the right alone was affected. All were women who had children. One was verified by *post-mortem*. Of 57 cases collected by Dr. R. 52 were in women, and the right kidney is far more frequently affected than the left. Child-bearing and tight-lacing were frequent causes of this affection. The valuable signs are the hard, smooth, sloping, rounded character of the swellings, and their mobility.

Removal of Lower End of the Rectum.—Prof. Nussbaum's (of Munich) case of removal of a portion of the rectum and prostate affected with epithelioma has made a great noise in surgical circles. It appears that, when cancer of the rectum removed by operation recurs, it does so after longer intervals than any other species of cancer. Dr. Nussbaum began the operation by making two semicircular incisions round the anus, and, carrying the finger upwards, he separated the healthy from the unhealthy tissues to the depth of

four inches. After four arteries had been tied, the bleeding ceased, and the bowel was then drawn down and secured to the skin. The man lived, it seems, three years after this operation, but succumbed to the same affection at last.—*Med. Press and Circular.*

CANNIBALISM IN NEW ZEALAND.—It was affirmed that the natives of New Zealand had abandoned their habit of cannibalism; but we hear that as late as June, 1868, some of the chiefs had eaten some soldiers killed by their followers.

CURE OF PHIMOSIS BY DILATATION.—Dr. Cruise, in the *Dublin Quarterly*, advocates this plan of treatment, which he regards as efficient, safe, and ready. He attributes the success of this method to the circumstance that the contraction is usually situated in the mucous membrane of the prepuce, just at its junction with the skin; consequently, when this contracted point is forcibly opened, the mucous membrane tears up, while the skin expands with the utmost facility. The operation may be performed with a pair of common dressing forceps, and Dr. Cruise gives a drawing of a three-bladed dilator he purchased in Paris; but he prefers an instrument he has himself constructed, in which the handles resemble those of a pair of scissors, whilst the blades are bent at right angles, and terminate in rounded points. These separate as the handles are approximated, the degree of separation being regulated by an arc and screw-nut between the handles. The degree of separation required may be estimated by casting a loop of thread round the glans penis, and so graduating the nut on the arc that on compression of the handles the blades separate sufficiently to tighten it. The preputial orifice is now sought out exactly where the skin and mucous membrane unite. The closed blades are introduced, care being taken to avoid the urethra, and the handles firmly and suddenly closed. The mucous membrane tears up in the line of the axis of the penis. The pain is said to be sharp, but transient; but no bleeding or other trouble follows. The foreskin should be at once retracted over the glans penis, and kept there for from twenty-four to forty-eight hours, the only dressing required being a piece of lint dipped in cold water.

CÆSAREAN OPERATION AFTER THE DEATH OF THE MOTHER.—Dr. Beckmann, of Berlin, has published the case of a woman, aged twenty-five, who, being in the eighth month of pregnancy, was seized with apoplectic symptoms, and died comatose. Conscious that there was no chance of saving the child unless it was extracted within five minutes after the mother's death, Dr. Beckmann, having obtained leave from the husband, performed the Cæsarean section with an abscess lancet, the only instrument he had with him. The child weighed hardly four pounds, and by persevering efforts at resuscitation, which were carried on for full two hours and a half, the child breathed freely, and is now a strong boy, nearly three years of age.

FUNCTION OF THE PONS VAROLII.—H. Nothnagel (*Virchow's Archives*) arrives at the following conclusions in regard to the *nervous centre of general convulsions*, which are derived from actual experiments. The centre of general convulsions is situated in the substance of the pons. Its lower boundary is corresponding to a section at the height of the inferior border of the pons. The faculty to perform the function of a centre of spasms is to be denied to the substance of the medulla oblongata.

Finally, he endeavors to prove that the spasms are produced by way of reflex. In some instances the section of the medulla oblongata had been made below the pons, the anima's remaining absolutely quiet. Again: the convulsions occurred if the section had left a portion of the pons connected with the medulla oblongata, showing the centre of action to be situated outside of the medulla.

At last the anatomical condition of the region of spasms is confirmatory of the view of reflex action. The region nearly corresponds to the situation of the gray nuclei and root-fibres of the sensitive cranial nerves. While the nuclei and root of the motor cranial nerves are near the raphe, those of the sensitive nerves are more lateral. The root-fibres of the portio major trigemini, in particular, descend, according to Schroeder von der Kolk, through the whole length of the medulla. This anatomical condition, it must be conceded, is no direct proof of a reflex action, but it renders it admissible and plausible.

From all this it seems that the convulsions following the injury of a defined region on the floor of the fourth ventricle are to be explained as spasms induced by reflex action.

AMOUNT OF FOOD CONDEMNED IN LONDON.—In the three markets in the city of London — Newgate, Aldgate, and Leadenhall—as much as 400 tons of meat are sold daily. About two tons of diseased meat are seized and condemned every week, and this is in the proportion of one part to 750. Last year the amount of meat condemned as unfit for food was nearly 129 tons, and in the preceding year it was more than 152 tons. It consisted of 6,440 sheep and lambs, 1,025 calves, 2,896 pigs, 9,104 quarters of beef, and 21,976 joints of meat; besides which there were also seized and condemned, on account of putridity, 19,040 head of game and poultry, 207 quarters of venison, and above 7,000,000 of fish, together with thousands of whelks, shrimps, periwinkles, &c.—*The Drug. Circ. and Chem. Gazette.*

THE "ANATOMY ACT" IN GREAT BRITAIN.—Not half enough subjects for dissection can be obtained in Great Britain on account of the stringency of the "Anatomy Act." Many of the London students go to France to dissect.

THE DOSE OF ARSENIC IN ECZEMA.—The formula given on page 34 of the last RECORD, in the article on the "Treatment of Eczema," by Dr. Erasmus Wilson, is a misprint. The quantity of "liquor arsenicalis" mentioned in the prescription should be a drachm instead of an ounce. We are particular in calling attention to the fact, in the fear that some one might prescribe the remedy as printed, without stopping to calculate the dose.

CLINICAL LECTURES ON THE DIAGNOSIS AND TREATMENT OF STRICTURE OF THE URETHRA.

By J. W. S. GOULEY, M.D.,

PROFESSOR OF CLINICAL SURGERY AND OF GENITO-URINARY DISEASES IN THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

LECTURE III.

INTERNAL URETHROTOMY.

GENTLEMEN:—The topic of to-day's lesson will be the treatment of stricture by incision.

When dilatation or divulsion is impracticable, the surgeon is obliged to recur to the knife, that the normal calibre of the urethra may at once be restored, and that the way may be prepared for the passage of full-sized sounds, which, as you know, is the most certain mode of maintaining the *calibration* of the canal. The operative procedures usually employed consist of dividing the stricture from within or from without. The one is known as *internal*, the other as *external urethrotomy*.

It is with the first that we shall now deal. It is done by introducing into the urethra a knife (*urethrotome*) with which the strictured part is incised, together with a little uncontracted tissue in front and behind. The design is to obtain union by granulation, and with the aid of dilating instruments to ensure the formation of a wide *cicatricial splice*.

The ancients, imagining that impediment to the flow of urine was generally due to what they called "carnosities," "excrescences," resorted to "escharotics," to sounds with "asperities" near their extremities, and sometimes to catheters with sharp eyes, or other cutting appliances at their points (Ambroise Paré).

In the latter end of the past century, Dr. Physic, of Philadelphia, employed the "lancetted stilette," and similar instruments were afterwards used by McGhie (1823) and by Stafford (1827). By means of the "lancetted stilette" the stricture was supposed to be punctured, but there was no certainty in that regard, as the point of the instrument was apt to deviate from the proper route, and make a false passage. This hazardous method prevailed for some time, but finally had to be abandoned.

In 1823 Mr. Civiale employed the "urethrotome," or "bistouri caché," to divide strictures in the fossa navicularis, and also to enlarge the meatus urinarius when too narrow to admit his lithotrite. Ashmead, and also Horner, had performed urethrotomy in the fossa navicularis as early, if not earlier, than Civiale.

In 1825 Amussat devised a urethrotome for the division of strictures in the deeper part of the urethral canal. His incisions amounted to little more than scarifications. He subsequently introduced two other instruments, the value of which was questionable, and they were never brought into general use.

In 1827 Dr. Jameson, of Baltimore, published in the *American Medical Recorder*, vol. xii., page 329, some "practical observations on stricture of the urethra," with a case treated by internal incision, and described a urethrotome of his own, with a plate of the instrument, a sketch of which I now show you* (Fig. 7). The following is substantially the description given by Dr. Jameson:—

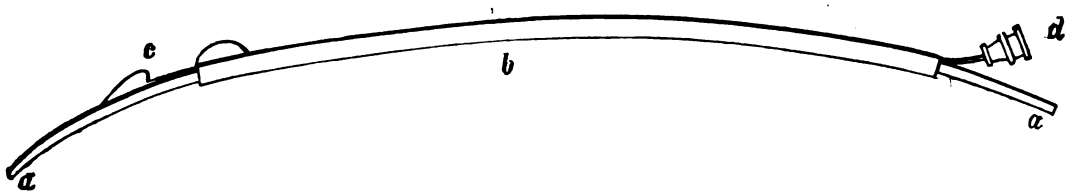

FIG. 7.

a. A small steel sound deeply grooved on its convex surface, about one-third longer than a common sound, to admit of the necessary movement of the sliding knife.

b. A silver tube of the same curve as the sound, about eight inches in length, having a guard at its vesical end to cover the knife.

c. The blade protruded.

d. Knob near the end of the staff, to protrude the blade.

This urethrotome, designed for cutting from before backward, does not differ very materially from some of the modern instruments. The small conducting steel sound was first passed through the stricture, and then the guarded blade introduced down to the obstruction, and the knife pushed onward.

In 1833 M. Reybard published, at Lyons, an essay on a "new procedure of curing strictures by incision" with an instrument having a short conducting gum bougie at its end, for cutting from before backward. This instrument was no great improvement over the lancetted stilette.

Maisonneuve's urethrotome, similar in its construction to that of Dr. Jameson, is the one now mostly in vogue (Fig. 8). It consists of a No. 1 deeply grooved curved sound (*B*), about twelve inches in length, with a small ring near its distal extremity as handle,—to its vesical end is screwed a fine gum conducting bougie of ordinary length (*C*),—and of a triangular blade (*A*), attached to a stem somewhat longer than the sound. From the base of the blade, near its point, project two lateral wings, which serve to retain it in the groove of the sound. The summit of the cutting edge is blunted so as to prevent injury to the normal mucous membrane. After many experiments with this instrument, upon the cadaver and on the living, it was found that the healthy urethral mucous membrane did not usually escape injury. On this account Voillemier made a modification of it, which he presented to the "Société de Chirurgie" of Paris in 1862. In the modified instrument, the blade is guarded by a plate of the same size and shape, and the summit is sharp, and not blunted as in the original.

I shall now give you the steps of the operation according to Maisonneuve:—

First, The conducting bougie is introduced past the stricture; this is no easy matter, for it is made of very soft material, that it may coil up in the bladder.

Secondly, The vesical end of the sound is screwed to

* I am indebted to my friend Dr. John G. Curtis, House Surgeon at Bellevue Hospital, for a number of the drawings which accompany these lectures.

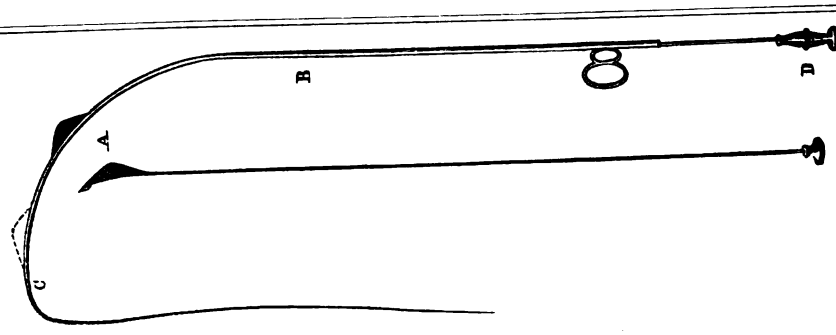

FIG. 8.

it, and the instrument is slowly and gently pushed onward, until it has gone beyond the obstruction, and can be moved back and forth without impediment.

Thirdly, The blade is made to glide into the groove of the sound until it has reached the part to be divided; the penis is then drawn forward, the sound steadied, and the cutting blade carried beyond.

Fourthly, The instrument is slowly and cautiously withdrawn, and the operation is thus terminated.

The operative procedure with Voillemier's instrument differs but slightly from the foregoing.

In 1849 * Civiale published an account of his instrument for retrograde urethrotomy (Fig. 9). The size of the flattened olivary extremity is such that considerable

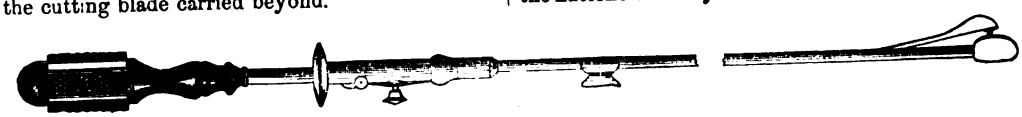

FIG. 9.

preliminary dilatation is necessary before it can be carried beyond the constriction. Sometimes, however, he used another instrument for scarifying from before backward to prepare the way for the retrograde urethrotome. The terminal olivary expansion is used as an explorer and serves also to guard the blade, which can be opened to the degree required. He does not claim any originality for these instruments, but thinks he has been happy in the combination of the elements of those which had before been in use, with the result of obtaining great precision in their action.

The "urethrotome à bascule" or "bistouri caché," made longer, and with a short cutting edge, I think answers a better purpose than the long instrument, for strictures of the pendulous portion. (Fig. 10, natural size, is copied from a drawing in his "Traité des maladies des organes genito-urinaires," 1858.)

Le Roy d'Etiolles' urethrotome for cutting from behind forward is little more than a scarificator.

Reybard, in his treatise on stricture, 1853, represents engravings of two urethrotomes for the retrograde operation,—one designed to dilate, and at the same time to make very deep and long incisions. He contended that the incisions, to prove serviceable, should

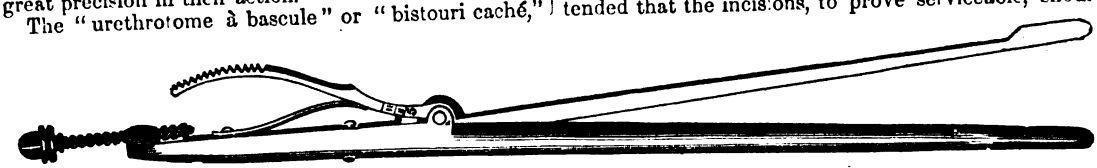

FIG. 10.

extend through the entire thickness of the spongy substance, and even into the subcutaneous connective tissue. An eye-witness to one of M. Reybard's deep internal incisions informed me that he had seen the blade protrude through the skin. Besides occasional excessive hemorrhage, abscess, and also infiltration of urine, have been known to follow this mode of operation.

I do not think that I shall have done my duty to you until I have entered my protest against the deep incisions of M. Reybard. His predecessors were at one extreme with their scarifications, and he has gone to the other with his long and very deep incisions. Scarifications are of no use; deep incisions are dangerous. Let us take the middle course, and make incisions free enough to reach the trouble. When the disease invades the whole thickness of the spongy tissue, with much induration, the internal division, immediately followed by free *divulsion*, is certainly preferable to these very deep incisions.

I have described to you urethrotomes for cutting from before backward, and from behind forward: both have been objected to, but a compromise has been effected by a combination of their essential elements in one instrument, that the two procedures may be practised at the same sitting. Ricord, Trélat, and others have introduced such devices, but perhaps the best is Charrière's (Fig. 11), which is a modification

* De l'urétrotomie ou de quelques procédés peu usités de traiter les rétrécissements de l'urètre.

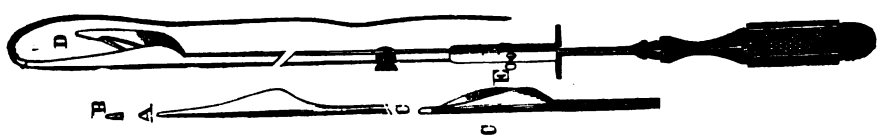

FIG. 11.

of Civiale's urethrotome. It is now used with Maisonneuve's gum conductor. The instrument is carried down to the stricture, the concealed blade is pushed forward so as to incise the constriction, and then, by a mechanism similar to Civiale's, it is tilted up and the stricture is divided in withdrawing the instrument a little. I would suggest the tunnelling of the point of this instrument, and that the whalebone guide be substituted for Maisonneuve's gum conductor.

Internal urethrotomy is done in the fixed or pubic curve as well as in the pendulous portion of the urethra. In France and in our country many prefer it to the other methods (in the pubic curve), while in Great Britain divulsion is almost exclusively used. My own preference is now for divulsion, and I only resort to internal urethrotomy in intractable strictures of the ante-scrotal portion of the canal.

I cannot do better than to give you some examples of urethrotomy in the sub-pubic curve, and in the pendulous urethra, from before backward and from behind forward, with different instruments. Please to bear in mind that success in this operation depends more upon the skill of the surgeon than upon the instrument he uses. A clean longitudinal incision should be made in the middle line of the urethral floor; sometimes a second one is done into the upper wall. Maisonneuve occasionally practises two lateral incisions.

TWO CASES IN WHICH URETHROTOMY WAS DONE WITH MAISONNEUVE'S INSTRUMENT.

Case I.—(*November*, 1865.) James O'D., aged 41. Seven or eight gonorrhœas; first attack in 1846, last in 1861. Retention of urine four times in the last three years. First symptoms of stricture eleven years ago. Had never been treated until he came to me, when it was impossible to pass even No. 1 through an obstruction three inches from the external orifice. At that time micturition was exceedingly painful, and the urine flowed guttatim. For two weeks repeated attempts at dilatation failed, and retention of urine was feared. Desosmeaux's endoscope revealed a glistening, nacreous-looking surface at the seat of stricture, through which a probe only could be passed. I then concluded to perform internal urethrotomy as soon as I could pass a conductor, and asked him to return in two or three days, but when he called he was suffering from retention of urine of twelve hours' duration. I endeavored to introduce Maisonneuve's conducting bougie, but failed. The urgency of the case was such that I could not postpone the operation to procure other instruments, so I coated with wax the milled end of Maisonneuve's steel director, and succeeded in getting it through the obstruction, then introduced the blade and made a free incision of the stricture, but no urine flowed. Another tight constriction six inches from the meatus was encountered and dealt with as was the first, but with much more difficulty. A full stream of urine gushed out, before I had time to pass a catheter, till one and a half pints had escaped. Hemorrhage moderate. Conical steel sounds Nos. 11, 12, 13, and 14 introduced successively. No anæsthetic. No catheter retained. In two days he called at my house, and I passed Nos. 15 and 16. No. 17 every second day for a month, then twice a week. No rigors. Not an untoward symptom. Catheterism subsequently carried to No. 18. August 23d, 1866, he called to introduce before me No. 17 conical steel sound, which he had used regularly every Saturday night since his dismissal. July 31st, 1868, the patient came to say that, having neglected to use his instrument for three months, and finding some impediment to its introduction three days before, he had used force, which was followed by considerable hemorrhage and frequent micturition (every half hour). He passed before me two ounces of bloody urine, with some straining and pain, but in a pretty full stream. No. 8 bulbous bougie entered a false passage in the sinus of the bulb, and when withdrawn half an ounce of blood flowed. Rest for two days, a diluent drink, and warm hip-bath, had the desired effect. On August 3d he was much better, no chill or fever. Sounds to No. 17 without impediment. He confessed that he had attempted catheterism while under the influence of strong drink. Has remained well ever since. Catheterism once a month. He returned in January, 1870; no difficulty was experienced in passing No. 17.

Case II.—Richard O., aged 42, of intemperate habits. This man was treated by me for urethritis in 1853. He has had in all seven gonorrhœas, the first in 1848, the last in 1861. In 1859 he was under my care for a tight stricture, which was dilated to No. 10; then I lost sight of him until March, 1866, when he came to say that he had neglected the use of instruments, and that he was suffering from dysuria. Urine was constantly dribbling from him, and complete retention was impending. No. 1 gum bougie gave him relief, and he was kept in bed for a few days to be prepared for urethrotomy. Incidentally I ascertained that, six years before, while climbing up a ladder, he had fallen astride one of the rounds, and that he had bled freely from the urethra for twenty-four hours, but had had no retention of urine. On the 10th of March, 1866, I explored his urethra and found a linear contraction half an inch from the external orifice, and another very narrow three inches back. The first was freely incised, and also the second, with Maisonneuve's urethrotome, cutting along the upper wall. I had found it impracticable to use the gum conductor, and after some delay and trouble inserted the grooved sound. A No. 12 conical steel sound was passed, and encountered another obstruction at the bulbo-membranous junction. The director (No. 1) was introduced as before, with difficulty, and without the gum conductor; then the blade was slid into the groove and passed down the urethra to divide the stricture,—this time along the floor of the urethra. Hemorrhage trifling. Sounds to No. 16. No catheter retained. He was sent to bed and catheterism ordered at intervals of a few hours for the first day, but he made water before this could be done. No chill or other unfavorable symptom. Once a day No. 16 was passed, and he was dismissed within two weeks. He afterwards returned twice a week, until early in May, to have the instrument introduced. June 1st, 1866, he was doing well and passing a good stream. Nos. 15 and 16. July 24th, 1866. Had been absent six weeks, and no instrument had since been used. No. 15 passed without impediment. The patient was last seen a year after the operation, and catheterism with No. 15 was done without trouble.

The difficulties which I had experienced in the two cases just related, suggested to me a device by which they might in future be obviated. The first and really difficult step of Maisonneuve's operation is to pass the gum conductor. I have seen the attempt made by clever surgeons, without success; and have often witnessed bending of the bougie in front of the obstruction, so that its point would appear at the external orifice. My success with capillary whalebone bougies induced me to employ them as conductors in urethrotomy, and I had but to adapt Maisonneuve's blade to the vesical end of my smallest-tunnelled sound, and I had a urethrotome of the simplest construction for cutting from before backward. The blade being sharp, both in front and behind the blunted summit, it could

also be used to cut from behind forward. It was not deemed necessary to give it as much curve as that of the tunnelled sound. The one I now show you (Fig. 12), is nearly straight, and I have experienced no trouble in using it, either in the sub-pubic curve, or in the pendulous portion of the urethra.

Fig. 12.

The operative procedure is as follows: First, the capillary whalebone conductor is passed into the bladder.—Secondly, its distal end is slipped through the smallest tunnelled sound, and way is made for the point of the urethrotome, and the sound is withdrawn.—Thirdly. The tunnelled urethrotome is introduced in a similar manner as is the tunnelled sound. The penis is steadied with the left forefinger and thumb, and the stricture divided by sliding the instrument gently upon the conductor until all resistance to its passage ceases.—Fourthly. The instrument is withdrawn, but the conductor left in position, that a large tunnelled catheter may be introduced, in order to ascertain if the incision has been sufficiently free, and at the same time to draw off the urine. Its practical application can be better illustrated by the citation of cases, which will also teach other points of importance.

Case III.—John G., aged 53, entered Bellevue Hospital, March 7, 1866. Gonorrhœa ten years previously. Narrow stricture in the region of the bulb. Dysuria. Frequent micturition. Retention relieved spontaneously. Dilatation persistently tried without success. On May 5th, 1866, after exploration, I injected half an ounce of oil into the urethra, passed a capillary whalebone bougie, introduced the tunnelled urethrotome (Fig. 12), and divided the stricture freely. No anæsthetic. No catheter retained. Sound No. 18. Hemorrhage very moderate. Hip-bath, rest, diluents, quinine, and iron. Slight febrile reaction on the following day, none afterwards. Catheterism every second day. Patient discharged on the 20th of May, and advised to continue the use of his sound. Has not since been seen.

Case IV.—Owen W., aged 33, admitted into Bellevue Hospital, February 19th, 1866. Gonorrhœa six years previously. Three retentions of urine. The first, one and a half years after the urethritis. Great suffering from dysuria, stream extremely small and twisted. Catheterism with small gum and other bougies had failed after numerous attempts. I first saw the man on May 12th, 1866, and, after a great deal of difficulty, succeeded in passing a capillary bougie through the stricture, which was situated in the subpubic curve. On the 14th I incised it freely with my urethrotome (Fig. 12), and passed No. 18 conical sound. No anæsthetic. Hemorrhage half an ounce. No catheter retained. Urine drawn off, for the first forty-eight hours. Hip-bath, diluent, quinine, etc. No chill or fever. Made a full stream of urine at normal intervals. Sound every second day. In a week the patient left the hospital, and has not since been heard from.

Case V. (Seamen's Retreat, June 10th, 1866.)—Louis G. G., aged 47. Urethritis at the age of 17. First symptoms of stricture (in 1857) twenty-one years after. In 1859 he had a swelling of the perinæum, and was operated upon by Mr. Michon, in Paris, but the patient could give no information regarding the operation. Whether he was urethrotomized, or simply an abscess was opened, I could not ascertain. He applied for admission at the "Retreat," on account of dysuria, and great frequency of micturition (every hour). Catheterism had been repeatedly attempted, without success, and was always followed by chills. Dr. T. C. Moffat, surgeon in charge of the hospital, requested me to examine the patient, and to do what I thought necessary. Bulbous bougie No. 10 revealed a constriction ¼ of an inch from the external orifice, another 2½, and a third 6 inches back, which proved to be extremely narrow. A capillary whalebone bougie was introduced into the bladder, and sufficient dilatation made with a tunnelled sound to admit my urethrotome, with which the strictures were incised deeply enough to admit No. 14 sound. Hemorrhage one ounce. No anæsthetic. No catheter retained. Urine drawn off. Chill in four hours, but none subsequently. Sound every second day. After the operation he was able to retain his urine three hours, and to pass a full stream. In a week Nos. 14 and 15. Slight hemorrhage. I saw him, from time to time, until November, when he left the hospital. I then lost sight of him, but he reappeared, April 17, 1867, when he complained again of dysuria, etc. He had neglected the use of his instrument. No. 7 could not enter the deep stricture. Capillary bougie, tunnelled sound to No. 7, and afterwards dilatation to No. 12, when he was again in a condition to pursue his occupation. He was kept under observation for several months, and finally went home to France.

Case VI.—Lawrence S., aged 28, was admitted into Bellevue Hospital, July 18, 1866. Two gonorrhœas, the first ten, the second four years before. First trouble in micturition (dribbling) in 1864. Several retentions. Dysuria. Stream thread-like, calls extremely frequent. Catheterism very difficult. The House Surgeon succeeded, after many attempts, in passing a gum bougie No. ¼, but when he wished to withdraw the instrument found it firmly held, about three inches back, and was obliged to make forcible traction to remove it; considerable bleeding ensued. The bougie was tied in a knot (Fig. 13), and the violence used to pull it out pro-

Fig. 13.

duced a laceration of the urethra at the seat of disease. Further attempts at dilatation proved useless. On August 4th, 1866, I introduced a capillary conductor, slid over it my urethrotome (Fig. 12), and divided the stricture from before backward, and afterwards discovered another constriction in the region of the bulb, which I also incised. The meatus urinarius was narrowed, and had to be divided. Very little hemorrhage ensued. No anæsthetic. No. 9 sound. Scalding in micturition. On the following day some swelling appeared in the prepuce; it increased so rapidly as to interfere with catheterism. On the fourth day there was considerable hemorrhage, besides a troublesome phymosis. After circumcision, the bleeding was found to have had its source in the frænum, which had been injured at the time the meatus was incised, and it was at once controlled by a pledget of lint. A gum catheter was introduced and retained 24 hours. In the excised prepuce there was found a little abscess, caused by infiltration of urine through the connective tissue of the frænum. These complications prevented the passage of dilating instruments, and on the tenth day No. 5 was with difficulty introduced. The tendency to further contraction soon became manifest in

the stricture of the pendulous portion. Accordingly, on the 3d of November, 1866, it was freely divided, from before backward, and from behind forward, with the same instrument, after the blade had been sharpened posteriorly to its blunted summit. Hemorrhage slight. No anæsthetic. No catheter retained. No. 10 sound. Subsequently dilatation was carried to No. 13, and the patient was discharged January 20, 1867, after having been instructed to pass his instrument at intervals of a week. I saw him six months after his dismissal; he was still using his sound, and was passing a normal stream of urine.

Case VII.—William H., aged 25, admitted to Bellevue Hospital, January 2d, 1867. Four gonorrhœas. During one of these attacks of urethritis he suffered much from chordee, and had the "chordee broken up" by a sharp blow with a book; free hemorrhage ensued. Persistent gleet. Dysuria. Several retentions. Failure of dilatation. Very narrow meatus. Stricture two and a half inches from the external meatus; another, very tight, five inches back. On April 7th 1867, free division of meatus with Civiale's "bistouri caché." Internal division of the two strictures with the tunnelled urethrotome. Hemorrhage inconsiderable. No. 14 conical sound. In a few hours he urinated, contrary to directions, without the aid of a catheter. No chill or fever. April 29th, No. 15 sound. Stream of urine normal. He remained under observation for several months, and was taught to pass a sound for himself.

Case VIII.—John P., aged 52, admitted to Bellevue Hospital, Jan. 3d, 1867. Three gonorrhœas; the first at the age of sixteen. Persistent gleet. Stricture of twenty years' standing, four and a quarter inches back. Contusion of perinæum, not followed by urethral hemorrhage, a year before admission. Dysuria. Very small stream of urine. Great frequency of micturition. Hemorrhoids. Dilatation to No. 8 in 1861. Neglect. Dysuria in 1863. No treatment since. When brought to the hospital in January 1867, he had complete retention. Catheterism with the smallest bougies failed, but after a hot bath he passed about a pint of urine in an interrupted, thread-like stream, in the course of an hour. On the following day the House Surgeon succeeded in introducing a gum bougie No. ½, and in gradually effecting dilatation till a catheter could be passed, when five pints of urine escaped, and shortly after three more pints. This sudden evacuation of such a large amount of water caused a severe attack of cystitis. Dilatation was persevered in, but up to March 24th nothing larger than No. 4 gum bougie could be introduced. April 13th, internal division with the tunnelled urethrotome. Slight hemorrhage. External orifice incised. Sounds to No. 16. No catheter retained. Urine drawn off for two days. On the third day slight febrile movement. Sound every second day. In a week small abscess in the scrotal walls. Three or four days after, another small collection of pus in upper and inner part of left thigh. "Phlegmasia alba dolens" of the left leg and thigh. The whole limb was enormously swollen, and presented the characteristics of what is called milk-leg in lying-in women. The enlargement gradually but slowly subsided, and he left the hospital, July 15th, 1867. No. 15. Oct. 9th, 1867, general health much improved. He had introduced No. 15 once a week since his dismissal. He called my attention to a number of varicose veins in the hypogastric region, which appeared soon after the swelling of the leg had subsided; some of these veins had increased to the size of the little finger. I could trace them from the left to the right groin. Pressure of the common trunk, in the right groin, to which they all converged, increased their volume by about one-third. It became evident to me that there was obstruction of the left iliac vein by a thrombus; this was the explanation of the "phlegmasia dolens." You will remember that in October, 1869, I exhibited to you the patient, and gave this explanation of his condition. His stricture had given him no trouble, he was passing his instrument once a week, but he suffered much at times from his cystitis.

Case IX.—Bellevue Hospital, April 22d, 1867, Charles W., aged 26, narrow stricture of two years' standing, six and a half inches from the external orifice. Failure of dilatation. Dysuria. Internal division with the tunnelled urethrotome. Hemorrhage two ounces. Sounds to No. 16. No catheter retained. Urine drawn off for two days. No rigor. Patient up on the sixth day. Was seen six months subsequently, when he could pass a normal stream of urine. Sound once a week.

Case X.—(May, 1866.) James M., aged 22, first and only gonorrhœa in January, 1865. Constant dribbling from overflow two months after, which compelled him to wear a urinal to keep his garments dry. The dripping of urine continued up to the time of his applying to me for relief. Stricture two inches and a quarter from the external orifice, which admitted but a capillary bougie. Gradual dilatation to No. 6. Urethra very sensitive. Rigors. No further progress. June 12th, endoscopic urethrotomy (according to Desormeaux). Incision insufficient. Deeper incision, with the tunnelled urethrotome (Fig. 12). Hemorrhage about half an ounce. No. 12 steel sound. No catheter retained. No chill or fever. June 16th, micturition every two hours, in a full stream. No disturbance at night. November 11th, 1868, the patient introduced before me No. 15 conical sound, without difficulty. He is now in the enjoyment of good health, and continues to pass his sound every two or three weeks.

My experience has led me to consider urethrotomy from before backward as a safe and proper operation, when skilfully performed, with the aid of a conductor, especially in narrow constrictions of the pendulous portion of the urethra. In strictures of the sub-pubic curve I would now do divulsion or the external division in preference.

The same objections made to Maisonneuve's urethrotome have been urged against mine. I have therefore followed Mr. Voillemier's example, and placed a guard over the blade (Fig. 14).

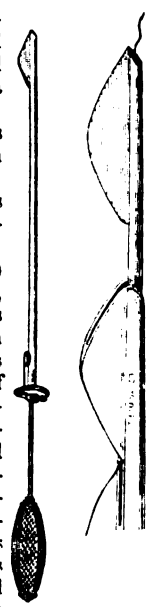

Fig. 14.

The present tunnelled urethrotome is straight, and designed for operations in the pendulous portion of the urethra.

I shall now give you some instances of retrograde urethrotomy in the antescrotal portion.

Case XI.—(Bellevue Hospital, 1860.) F. B., aged 47. Impassable stricture, from gonorrhœa, three and a half inches from the external orifice. Dribbling from overflow. Abscess at the root of penis (right side). Impending retention of urine. External urethrotomy in the perineal region. A narrow stricture encountered in the region of the bulb, and freely divided. The current of urine having been turned, the first stricture became permeable, and was gradually dilated to No. 8, but no further progress could be made. In three months this stricture was freely divided, from behind forward, with Civiale's urethrotome (Fig. 9), and sounds to No. 14 introduced. Went away at the end of a month, and was

not seen by me until four years afterwards, when I explored his urethra, and found that the stricture had recontracted to a very considerable extent (from neglect). I advised him to submit to a course of dilatation, but he did not return. He was readmitted to Bellevue Hospital, and divulsion was finally resorted to, with a good result.

Case XII.—(June, 1866.) Robert M., aged 36. Old stricture, with urinary fistulæ. External perineal urethrotomy. Internal urethrotomy (retrograde) with Civiale's "bistouri caché," for a stricture one and a half inches from the external orifice. Slight hemorrhage. No. 13. No catheter retained. Good result.

Case XIII.—(June, 1866.) James W., aged 38. Dense stricture of two years' standing, one and a half inches from the external orifice. Retrograde urethrotomy, with Civiale's "bistouri caché." No. 18 sound. Moderate hemorrhage. No catheter retained. No rigors. Good result.

Case XIV.—(February 28th, 1868.) John D., aged 18. Three gonorrhœas. The first two years before. Dysuria and dribbling since three months from the first urethritis. Rigors every day. Meatus urinarius contracted, indurated, and very sensitive. Two narrow strictures, 2½ and 5½ inches back. Capillary bougie and tunnelled sounds Nos. 3 and 4. Gum catheter retained twenty-four hours. Sounds Nos. 7 and 8. The constriction 2½ inches back was very dense, and would yield no farther to dilatation. Rigors. Meatus incised. March 13th, retrograde division of the stricture of the pendulous portion with Civiale's urethrotome (Fig. 9). Hemorrhage half an ounce. No anæsthetic. No catheter retained. No. 12 sound. Scalding in micturition, but no chill or fever. Good stream of urine. The deeper stricture gradually dilated. In two weeks he left town, and could then pass a No. 12 sound, which he was using once a week, six months after, when he was last heard from.

I shall now give you the details of the case of congenital stricture operated upon January 11th, 1870.

Case XV.—Lewis H., aged 32. Temperate, married, one child. Has never had venereal disease. Had congenital phimosis; the aperture in the foreskin was of the calibre of a "darning needle." From infancy he had had trouble in micturition. He said that during urination he had always had a sensation as if "a string had been tied around the penis, about three inches from the end." The stream of urine was gradually diminishing in size, and he was compelled to strain much at times to pass it drop by drop, but had never had retention. For the last five years he had had a gleety discharge. He once had slight hemorrhage during micturition, and from that time he thought the constriction of the urethra was gradually extending farther back. In the fall of 1869 he was circumcised, and his condition somewhat improved, but his medical attendant discovering a narrow stricture at the meatus, sent him to the city for treatment. Penis normal. External orifice indurated; would admit but a small probe, which could be carried back three inches without impediment. After free incision of the meatus, bulbous bougie No. 2 arrested at 1½ inches. No. ½ showed a long constriction, which extended back to the peno-scrotal junction. A blunt-pointed, narrow, straight bistoury was introduced, and the canal incised, from the peno-scrotal junction to the external orifice; then Civiale's bistouri caché was used to make a freer division. No. 10 to the peno-scrotal junction. No anæsthetic. Very little hemorrhage. Quinine, etc. Gum catheter No. 5½ retained twenty-four hours. You will remember that I considered the incision near the peno-scrotal junction as insufficient, inasmuch as the sound No. 10 would not go beyond that point; therefore, on the sixth day, I resorted to divulsion, with result of introducing No. 10 into the bladder. By an oversight, no quinine was given. Rigor. No fever. Slight hemorrhage. No catheter retained. Good stream of urine three times a day. No. 10 every second day. He went home on January 28th, and his physician now passes the instrument twice a week.

It is scarcely necessary for me to speak again of the indications and contra-indications of this operation, for I believe I have made them sufficiently clear to you.

The dangers have already, in an incidental way, been alluded to, and I shall now only name some of them in the order in which they usually occur. Hemorrhage is apt to follow the very deep incisions, likewise in filtration of urine and abscess, but pyæmia may supervene upon the merest scarification.

I have been very fortunate in my fifteen operations, for, though a serious complication—thrombosis (Case VIII.)—has been encountered, I have no fatal result to report. Relapse followed in some cases, but the cause was evident, and it need not generally be feared if catheterism is continued at intervals of from one to four weeks.

The subject of internal urethrotomy will be terminated at our next meeting, when the treatment of strictures in the fossa navicularis and at the external meatus will be discussed.

Original Communications.

THE HISTORY AND USES OF BELLADONNA.

READ AT THE LAST ANNUAL MEETING OF THE ONONDAGA MEDICAL SOCIETY,

By WM. T. PLANT, M.D.,

OF SYRACUSE, N. Y.

In looking over our medical journals, I have often noticed the frequent reference made to belladonna, and its derivative, atropine. While the standard works give but little space to its consideration, we scarcely take up a medical paper that does not pay some fresh tribute to its remedial powers.

That a medicine which was known to the ancients, and which has never been quite lost sight of by the profession, should receive in these latter days so many favorable notices, would seem to argue that, notwithstanding the experience of ages, there is still something worth while to be learned concerning it.

In preparing this article, no originality is aimed at; I only purpose to put the recorded experiences of others into a connected and available form, at the same time giving such items of history as I have been able to meet with in the books and journals at my command.

Belladonna grows, or can be grown, in all temperate latitudes. Botanically, it belongs to a large family, the genus Solanum, remarkable for the variety of its species. It includes the most nourishing esculents and the most deadly poisons. The potato, the egg-plant, the tomato, bitter-sweet, henbane, stramonium, and the deadly night-shade, are all brethren of the same family.

It has been described by ancient and modern writers. During the 16th and 17th centuries it was called "Solanum furiosum," probably from the peculiar delirium excited by it. In Macbeth, Shakespeare is

thought to have referred to it by the name of "insane root." After the witches had vanished from sight, he makes Banquo ask: "Were such things here as we do speak about? Or have we eaten of the insane root, that takes the reason prisoner?"

An old author says, "It is called Bella-donna from the Italian ladies using it to take away the too florid color of their faces." Its popular name of deadly night-shade is of German origin, and sufficiently indicates its dangerous character. All parts of the plant are actively poisonous, though only the leaves are officinal. It is highly ornamental, often growing in shaded places, and is sometimes cultivated. Its graceful flowers are succeeded by a berry, which, when ripe, is of a dark purple color, having a sweetish taste, and closely resembling a cherry. These alluring characters have led to many cases of accidental poisoning. In some instances, large numbers of men have simultaneously been rendered delirious by it. Plutarch relates that when the Roman army under Antony was retreating from the Parthians, provisions became so scarce that they were constrained to venture upon any vegetable to be had. "Among others, they chanced upon an herb that was mortal, first taking away all sense and understanding. He that had eaten of it remembered nothing in the world, but employed himself in moving great stones from one place to another, with as much earnestness and industry as if it had been a business of the greatest importance. Through all the camp men were seen grubbing upon the ground with stones which they carried from place to place." These remarkable and very likely exaggerated effects upon the Roman soldiery have been attributed to this plant, since no other poison known produces a delirium of so fanciful a nature. History tells how the Scots mixed the juice of belladonna with the food with which, by agreement, they were to supply the Danes, and how the latter became so intoxicated that the Scots killed the greater part of their army. Orfila gives an instance where a hundred and fifty soldiers exhibited all the symptoms of poisoning, and finally recovered. This tendency to recovery after the most alarming symptoms should not be lost sight of in judging of the value of antidotal measures. In many cases, complete recovery has taken place without resort to remedies, where large quantities of the poison have been ingested.

The symptoms of poisoning by this agent are well-marked and tolerably uniform. They are, extreme dilatation of the pupils, a remarkable dryness and constriction of the mouth and throat, giddiness, and a delirium which is usually of an extravagant and pleasing character. If a fatal dose has been taken, the face becomes flushed and tumid, vision is lost, the stomach and bowels are insusceptible of impression, feeling is abolished, and the whole nervous system paralyzed.

Though belladonna has been known and used for centuries, the isolation of its active principle has been reserved for modern science. The discovery of atropine appears to be due to Brande. All parts of the plant yield it, but in very small quantities, an ounce of the root giving but about one grain of the alkaloid. It is an agent of extraordinary energy; two-thirds of a grain have produced the most alarming symptoms.

In order to comprehend the peculiar adaptability of this agent to certain diseased conditions, it is necessary to understand something of its physiological action. Recent experiments have added largely to our knowledge of this branch of the subject. Dr. Harley, of King's College Hospital, gave physiological doses to man, the horse, and the dog. After a short time the pulse was increased in frequency, force, and volume, with an increase of temperature. These were prominent and constant symptoms. Dr. Brown-Séquard has *seen* a diminution of the calibre of the blood-vessels in the membranes of the spinal cord after belladonna, thus proving that it excites the capillaries to contraction. It has also been shown to be a powerful excitant of unstriped muscular fibre. These effects are considered due to a stimulation of the sympathetic nervous system. Dr. Richard Hughes regards it not only as an excitant of the sympathetic, but a depressant of the cerebro-spinal system. The characteristic dryness of the throat he considers due to a depressing influence on the pneumogastric; its action in whooping-cough or asthma may be explained in the same way.

The therapeutic applications of this agent are various and important. We notice, first, its use in poisoning by opium.

Contrary to general opinion, a knowledge of the antagonistic properties of opium and belladonna seems to be of early date, though lost sight of until revived a few years ago. As early as 1570 we are told of Italian pedlers who excited the wonder of the common people by giving the root of belladonna to alleviate thirst. Its noxious effects were averted by vinegar, wine, or *theriaca*, the latter being a preparation of opium in common use at that day. In 1661, a man who had swallowed a spoonful of the inspissated juice of night-shade root recovered after using theriaca and juice of rue. In 1677, Faber writes of thirteen persons poisoned by eating belladonna berries, ten of whom were treated by theriaca. Again, in 1776, two of five cases of poisoning by this herb were treated by opium.

Within a few years, the mutually antidotal properties of these two agents have been so often shown as to deserve general belief. In several particulars they are quite opposite in their effects on the system. For instance: Opium contracts the pupil; belladonna dilates it. Opium produces constipation; belladonna relaxes the bowels Opium produces deep sleep; belladonna tends to wakefulness and extravagant fancies. Children are very readily affected by opium, while they are remarkably insusceptible to belladonna, and sometimes bear very large doses before cerebral symptoms and dryness of the throat are produced. In 1859 Dr. Fuller gave it as a rule, that the younger the child, the larger the proportionate dose of night-shade required to produce its physiological effects; every one knows that with opium the reverse is true. A proof of the antagonism of these agents is also furnished by those cases, of which several are on record, where mixtures containing poisonous quantities of both opium and belladonna have been swallowed without producing, to an alarming extent, the baneful effects of either.

The plan of giving belladonna as an antidote to opium has been attended with such gratifying results that it is fast becoming the established practice. From the numerous cases reported, I select the following: Two are recorded in the London *Lancet*, 1868, where ten drops of the tincture were given every half-hour. In one of these, in which about an ounce of laudanum had been taken, the pupils did not begin to dilate until one hundred and ninety drops were administered.

An infant five weeks old had taken nearly a drachm of laudanum. The surface was livid, and pulse and respiration were nearly suspended. Fifteen drops of belladonna tincture, every fifteen minutes until about a drachm had been given, saved the child.

In 1862, Dr. Wm. F. Norris, of Philadelphia, gave in the aggregate seventy-five grains of the extract of belladonna to a young man who had swallowed the greater part of a drachm vial of morphia. In this case galvanism and the shower-bath were also used, and the man finally recovered.

A readier way of influencing the system in desperate cases of narcotism is by the subcutaneous injection of atropine. Several striking and beautiful examples of the success of this plan have lately been communicated from authentic sources. In one case the lips were livid, respiration was reduced to seven, the pulse was gone, there was frothing at the mouth, and the case looked hopeless. One-sixtieth of a grain of atropine was thrown under the skin. In fifteen minutes its effects were perceptible in the dilating pupils and more frequent respirations. In thirty minutes another sixtieth was introduced. Recovery was complete in two-and-a-half hours. The foregoing case resulted from the hypodermic use of half a grain of morphia.

Professor Wilson, of Chicago, gives in the *Journal of Mat. Medica* an instance where a quarter of a grain of atropine was injected under the skin for poisoning by morphine. Almost instantly the contracted pupils became dilated, the stertorous breathing was replaced by a hurried respiration, and the patient soon recovered.

A remarkable case was communicated to the MEDICAL RECORD, last year, by Dr. Buttles, lecturer on Gynecology at the University Medical College, New York. In a woman, aged thirty-eight, symptoms of poisoning came on after the hypodermic use of fifteen minims of Magendie's solution. She soon stopped breathing. Artificial respiration was resorted to, and kept up for an hour and a half after life seemed extinct, when, at the suggestion of Dr. Budd, one-sixtieth of a grain of atropine was thrown under the skin. In fifteen minutes there were signs of life, and the pupils began to dilate. In twenty-five minutes she began to breathe, and was soon beyond danger. These are but few of many such cases recently reported. I believe that incomparably the best treatment for desperate cases of narcotic poisoning is by the subcutaneous use of atropine, and that no case should be regarded as hopeless, while life remains, until this expedient has been tried; for of the antagonism existing between these drugs there can be no question. In a paper on their mutually antidotal properties, published in the Transactions of the State Medical Society for 1865, Dr. Downs truly remarks, "that when we find the stomach harboring from ten to fifty grains of extract of belladonna, or fifteen to twenty grains of muriate of morphia, without any injurious effect being manifest, it will naturally suggest itself to the practitioner that some latent principle is at work, exerting a controlling influence upon the noxious drug and neutralizing these otherwise potent elements." In these cases, then, the antidote may be, and often must be, given in doses that would be hazardous under other circumstances. The rule would seem to be, to use it largely, frequently, fearlessly, until it produces its specific effect upon the pupil, the throat, or the brain.

After what has been said of the reciprocally antidotal properties of these drugs, we hardly need call attention to the treatment proper to be pursued in poisoning by belladonna or atropine. The last edition of our Dispensatory states that it would be unsafe to rely on opium to the exclusion of other measures. But we would say, use such other measures as may seem proper, but let the main reliance be on opium; give it promptly and freely, either by the mouth or skin, and preferably the latter. A number of cases of belladonna poisoning have been put on record where the adoption of this plan has been followed by recovery from a desperate condition.

In one case of poisoning by this drug, occurring in 1864 at the hospital in Prague, the Calabar bean was given as an antidote with success. As opium and the bean are both strongly myotic in their action, it is not improbable that the similarity extends to other effects.

As a remedy in that obscure class of affections known as neuralgias, belladonna enjoys a reputation next to opium. In the obstinate disease known as tic douloureux it has many times been employed successfully where other means have been faithfully and unavailingly tried. For the relief of all the lighter forms of neuralgia it is often effectual. Sometimes the endermic or hypodermic use of atropine succeeds where other methods fail.

For that troublesome affection known as irritable uterus, and for the nervous pains attending the menstrual period, belladonna enjoys a celebrity second to no other remedy. Dr. Burne, author of a work on constipation, alludes to the efficacy of belladonna in painful menstruation in the following terms: "I have usually prescribed it in the dose of a quarter of a grain of the extract where patients suffer for two or three days about the menstrual period. In urgent cases I advise it to be repeated in an hour, then in two hours, and so on until two, three, or four doses have been taken, and I have seldom been disappointed in the result. The following combination has been considerably used in irritable dysmenorrhœa, and is highly spoken of:

"℞. Camphoræ, ʒ ijss; Quiniæ Sulph., Ext. Belladonnæ, āā ʒ ss. Ft. pil. No. 80. Two to be taken hourly until the pain ceases."

Although the use of night-shade in epilepsy has been well-nigh superseded by the bromides, yet it is well not to lose sight of the fact that numerous tributes to its value in this affection have been published, and that it has sometimes succeeded when all other means have failed. In 1842 a French physician reported two hundred cases treated by this remedy, and from the Vienna Hospital eighteen cases are reported. Occasionally, permanent cures were effected; and generally the violence and frequency of the fits were lessened. But in recent cases only did the remedy appear to have more than a transient effect. In reading accounts of its employment in epilepsy, one is impressed with the similarity of action to the bromides. Frequently the fits are suspended for weeks or months, but they generally recur, and the disease acquires, at length, a tolerance of the remedy.

Tetanus is one of the diseases in which belladonna has often been employed, sometimes successfully. From its action in diminishing the vascularity of the cord, it would seem to be indicated in this disease, particularly for the relief of the opisthotonos; but, from published cases, we must conclude that the ordeal bean and nicotine are much more efficient agents. When given in tetanus, large doses are borne and required; a moderate quantity—say half a grain of the extract—may be given first, to be repeated soon, and increased as fast as the system shows its tolerance. In one case the remedy was thus pushed until five grains of the extract were given at once; in another, four; both recovered.

As a remedy for whooping-cough, belladonna has been known at least since the early part of this century, for in 1810 we have an account of thirty cases said to have been cured by it between the eighth and fifteenth days. Many favorable notices have since been published, and its value in certain stages of the complaint is now generally conceded. Dr. Fuller, of St. George's Hospital, combats the common opinion that pertussis must run a certain course. Treated by his method he rarely finds the whoop to last more than twenty-one days, and sometimes not more than ten. He uses gradually increasing doses of belladonna and sulphate of zinc. Professor Jacobi, of New York, prescribes for children six or eight months old, a sixth of a grain of extract three times a day; for those

three or four years old, half a grain. Given in these doses, he says the effect on the pupil or on the brain will hardly ever be perceptible. Dr. Valentine Mott was accustomed to prescribe belladonna in this disease in the following combination:—

℞. Acidi hydrocyan.....gtt. vi.
Ext. belladonnæ.....grs. ij.
Tinct. opii camph..... ʒ iij.
Syr. tolutani..... ʒ i.
Aquæ..... ℥ iij. M.

S.—A tablespoonful four times daily.

Without any opportunity to test the medicine in this disease, I am led to believe, from reports that I have read, that belladonna is in some way, probably from a depressing influence on the pneumogastric, capable of relieving and lessening the duration of whooping-cough; that in the early stage it is not of much value; that some epidemics are more amenable to it than others; and, finally, that it is as well adapted to the treatment of some other forms of cough—such as are thought to be dependent on an irritation of the par vagum—as to whooping-cough.

About the beginning of the present century, the author of Homœopathy announced belladonna as the natural cure, as well as preventive, of scarlet-fever, because, like this disease, it produces an affection of the throat and a cutaneous efflorescence. Since that day it has been given to thousands of children to test its prophylactic power, and, as often happens in medicine, the most contradictory reports come to us from observers equally intelligent and honest. For instance, Lehmann tried it faithfully in epidemics of scarlet-fever, and concluded that it was destitute of protective power. Dr. Alley, of the Orphans' Asylum, Boston, came to the same conclusion, after extensive trials; while its prophylactic virtues have been affirmed by those great men, Hufeland in Germany, and Guersant in France. From the fact that very many of those rendered liable by exposure do not take the disease, it is difficult to estimate the value of preventive measures. That *some* who have been subjected to prophylactic treatment have had the disease in its usual form and severity, goes very far to disprove the theory of Hahnemann. In 1851, Benjamin Bell, of Edinburgh, gave belladonna daily to fifty-four boys in one institution. Twenty-three cases of scarlet-fever occurred in this group. Probably this proportion is quite as large as will be found in most epidemics. Each of these boys took the drug for a month before the disease appeared among their number, so that there was ample time for the system to be fortified by its full preventive power.

In the treatment of scarlet-fever, particularly in the anginose variety, it has much testimony in its favor, and is undoubtedly a valuable remedy, though not in very general use. Professor Benson, of Louisville, treats the throat affection by inunction of the submaxillary and parotid regions with fifteen grains of the extract to the ounce of cerate. Others prefer its internal administration, giving it in small and frequent doses throughout the disease. By its influence on the capillary circulation, as noticed by Claude Bernard and other experimenters, it probably equalizes the circulation, and favors the appearance and continuance of the eruption.

Incontinence of urine, arising from weakness or paralysis of the vesical sphincter, is more certainly and speedily subdued by belladonna than any other remedy. Some difference of opinion has obtained respecting its mode of action in this complaint. The most reasonable theory seems to be, that by virtue of its property of stimulating the sympathetic nervous system, it causes contraction of those sphincters and muscular fibres that receive their nervous supply from that source. This view of its action is strengthened by the fact that it has the same influence over the sphincter ani as over that of the bladder, for in that rare affection, incontinence of fæces, we have accounts from the French of perfect success with this agent after failure by other means. That it possesses a decided and happy power in those troublesome states in which the sphincter of the bladder is at fault, may be readily proven by prescribing it for the first elderly person who complains of an indisposition in the sphincter to contract after urination, or to the first child troubled with nocturnal forgetfulness. Professor Jacobi says this trouble in children is almost always easily removed by belladonna. A complete cure was generally obtained in a week or less by the same doses as above recommended in whooping-cough.

Many years since, it was discovered that night-shade often acts as a laxative, but its employment for that purpose is of recent date. Its use in habitual constipation, to give tone to the intestinal tube and enable it to propel its contents without the spur of cathartics, logically follows a knowledge of its stimulant action on the nerves of organic life, by which the intestinal muscles are animated. This application of the remedy is an important one, and claims a moment's attention. In a case of facial neuralgia, recorded in the tenth number of Braithwaite, the extract, in small doses, acted as a purgative, which croton oil had failed to do. In a case of obstruction, where oil and clysters were employed for a week without result, half a grain of the extract every fourth hour, with belladonna ointment to the abdomen, produced free catharsis after four doses. In a paper read before the British Medical Association three years ago, Dr. Fleming strongly advises atropine to increase the peristaltic action of the bowels. He uses it in conjunction with sulphate of magnesia and aromatic sulphuric acid, and claims more than usual success in treating constipation by these means. I have lately used with good results a formula given in the RECORD, by Dr. Thompson of New York, as follows:

℞. Extract. belladonnæ.....gr. ¼.
Extract. nucis vom.....gr. ½.
Extract. colocynth comp ...gr. iij.

To form one pill, to be taken at night. Another may be taken in the morning, if necessary; but one soon becomes enough.

Prominent among the peculiarities of this most peculiar medicine is its property of arresting the secretion of milk. In this respect no agent known to the profession acts with so much energy and certainty. In all those accidents and conditions that make it desirable to prevent, diminish, or arrest the lacteal secretion in both breasts or in one, belladonna extract, rubbed up with water and applied to the areola, will usually effect the object. When the gland becomes inflamed, abscesses may often be prevented by a timely resort to the same treatment. Professor Storer's favorite prescription to inflamed breasts consists of ext. belladonna and sweet cream, equal parts. As, by its local application, one pupil can be dilated without affecting the other, so the secretion of one gland may be suspended while the other continues active.

The peculiar dryness of the mouth and throat caused by this agent has suggested its employment in ptyalism from mercury or other cause. I have had no opportunity to test it in this affection; but two physicians of this city have assured me of its efficacy in diminishing the salivary secretion.

In a lecture before referred to, Dr. Harley says this plant should stand at the head of all our stimulants, for no medicine in the Materia Medica approaches belladonna in its simple, direct, immediate, and powerful influence in exalting the force and rapidity of the heart's action. Regarding it as a stimulant to the organic nervous system, he considers that in all conditions where there is a depression of this kind of nervous influence, such as fainting from weakness or shock, the collapse of cholera, failure of the heart's action from chloroform or other cardiac paralyzers, the subcutaneous use of atropine is the most reasonable and hopeful means of resuscitation. I was lately consulted in a case of preternatural slowness of the heart's action occurring in a middle-aged man, usually quite well. I suggested fluid extract of belladonna as a cardiac stimulant. Ten drops were given three times a day with marked benefit. The pulse very soon rose from forty to sixty beats per minute, with great relief to the feelings of debility. The effect of a belladonna plaster in quieting a palpitating heart has long been known, and ascribed to a sedative action. May it not rather act as a stimulant, toning up the organ to do regularly and thoroughly the work that before it could only perform irregularly and incompletely?

Claude Bernard has shown that belladonna and the ergot of rye diminish the quantity of blood in the membranes of the spinal cord, and advises their use in inflammations and congestions of that organ. Paraplegia, depending on hyperæmia of the cord for its cause, would call for the same remedies. Claude Bernard's treatment for chronic myelitis is by ergot internally and the belladonna plaster externally. He states that his success has been greater than he had dared to hope for.

To the ophthalmic surgeon, belladonna is invaluable. In whatever way used, one of its first effects is to dilate the pupil. The introduction of atropine into ophthalmic practice a quarter of a century ago has left nothing to be desired as a mydriatic, since it is painless, cleanly, certain, and prompt. Whether the object is a continued dilatation to prevent or break up adhesions between the iris and the lens; to prevent the iris from protruding through an aperture in the cornea caused by wound or ulcer, or a temporary dilatation to facilitate operations, the solution of atropine meets every requirement. In case the dilatation continues too long, the Calabar bean extract may be applied to produce contraction. Both belladonna and atropine have been employed and extolled in the treatment of ordinary inflammations of the eye. A writer in the *British and Foreign Medical Review* says: "In our experience, few cases of scrofulous ophthalmia have resisted the careful use of a belladonna collyrium, and in many other varieties of inflammation of the eyes it proves scarcely less useful. For the intolerance of light that so frequently accompanies diseases of the eye, it is our surest relief. Even in some old and inveterate cases of photophobia, it will act most beneficially. Its internal use in cases of orbital neuralgia, resulting from over-use of the organ, is highly recommended."

In many other morbid states, belladonna has proved extremely serviceable. Such are the nervous vomitings of pregnancy, spasmodic asthma, especially where the dyspnœa is paroxysmal, with little or no secretion. And particularly is it useful in those affections about the anus, such as hemorrhoids, fissures, and fistulæ, that frequently cause spasm of the sphincter and excruciating pain. I have repeatedly seen prompt relief attend the application to inflamed hemorrhoids of an ointment made strong with belladonna and tannic acid, and I have lately seen recommended for the *cure* of this troublesome disorder the daily administration of fluid extract of night-shade in doses of two and a half drops. From its tendency to keep the bowels soluble by relieving the congestion of the over-distended intestine, I believe this application of the drug to be a very important one.

In spasm of the urethra, suppression of urine, rigidity of the os uteri during labor, chorea, gastralgia, and albuminuria, it has occasionally been employed with success. From its influence over the capillary circulation we would consider it applicable to the treatment of hæmoptysis. I can find but one reference to its employment in that disorder, and that is by Schroeder. His plan was to throw the dried leaves upon burning coals, allowing the patient to inhale the fumes; he reports success in all cases.

In concluding this paper, we have to offer as the result of our researches the following conclusions:—

1st. Belladonna and opium are mutually antagonistic and antidotal. In poisoning by either, the administration of the other should be held as a part of the established practice; and the antidote should be proportioned in quantity to the amount of the poison ingested. Especially is the hypodermic use of atropine or morphine applicable to desperate cases.

2d. Children will bear, and often require, proportionally larger doses of belladonna than adults.

3d. In neuralgias, epilepsy, and tetanus, it is occasionally most happy in its effects.

4th. In whooping-cough it has more testimony in its favor than any other remedy, and frequently shortens its course by many days.

5th. Its prophylactic power over scarlatina we regard as not proven, though it is a valuable remedy in the treatment of that disease.

6th. In incontinence of urine from a weakened or paralyzed sphincter, in paraplegia, and the whole train of symptoms attending irritation or inflammation of the cord, it is a medicine of the highest value.

7th. To the relief of habitual constipation it is better adapted than any of the usual remedies, because it directly unloads the distended capillaries and stimulates the relaxed muscular coat to contraction.

8th. In its influence over the mammary secretion it stands almost alone and unrivalled.

9th. In spasmodic contraction of all sphincters, and in spasmodic diseases generally, it is a most useful agent.

10th. Many morbid states of the eye are successfully treated by belladonna; among these, iritis and photophobia may be particularized.

11th. Lastly, this plant has properties peculiarly its own, which give it a special value, and therefore it is worthy of being better known and more used.

The Mount Sinai Hospital, N. Y.—During the year 1869, 648 patients were received into this institution. There were treated 906 out-door patients. Of those treated in the hospital there were—discharged cured, 510; improved, 71; not improved, 7; left before treatment commenced, 3. Total, 591. Died, 47. The average number of patients, 48½. The average time of residence in the hospital was 10 days. Prussia and Russia furnished 402 patients. The principal occupations of these in-patients were: domestics, clerks, glaziers, pedlers, tailors, housekeepers, and laborers.

Hôpital Lourcine.—Two thousand female syphilitic patients are treated yearly at the Hôpital Lourcine, Paris. Mortality, 1 in 27. Here the non-mercurial treatment is carried out to a great extent.

A PIN ENCYSTED IN THE WALLS OF THE HEART.*

By D. R. AMBROSE, M.D.,

ONSLOW, C. H., N. C.,

LATE HOUSE PHYSICIAN OF CHARITY HOSPITAL.

A NEGRO woman, forty years of age, reduced by an illness of six or eight months to a state of great emaciation, died after a few hours of intense pain, suddenly brought on by an effort to turn from her back upon her side. The autopsy showed that fatal peritonitis had been induced by escape of the contents of the stomach through a perforation of the anterior wall, an inch in diameter, situated about two inches from the pyloric orifice.

The case is presented on account of the following unusual discovery in the heart:—

On taking the organ in my hand, a hard and pointed substance was felt near the apex of the right ventricle, directed downwards and inwards (towards the median line of the body). On opening the ventricle, I felt the inner extremity of this foreign body near the apex and just beneath the endocardium. I now carefully dissected away the flesh until I had fully exposed this foreign body throughout its whole length, and found it to be an ordinary pin closely encysted, and completely traversing the whole thickness of the ventricular wall, with its point covered only by its own cyst and the visceral portion of the serous layer of the pericardium.

The head was covered by its cyst and endocardium. The pin had become brittle so as to break from slight pressure in manipulating the organ before I dissected it out. There were no symptoms of inflammation, nor of irritation of the heart; no hypertrophy; no dilatation, and no valvular lesions.

The pericardial cavity contained about an ounce of serum, but no lymph or pus.

The husband of this woman told me that she swallowed a pin nine years ago, from which she never had any trouble.

DELIRIUM TREMENS.

By E. P. BENNETT, M.D.,

DANBURY, CONN.

IN consequence of the diverse and conflicting opinions entertained by physicians regarding the treatment of delirium tremens, I am satisfied that the true nature of this disease is not well understood by many in the profession, and still less by the public at large. If a man addicted to the immoderate use of intoxicating beverages becomes wakeful, excited, and finally delirious, he is at once set down as having delirium tremens, and attacked with stimulants and opiates in the most heroic manner, without the least regard to the condition of the circulatory system or anything else. The idea with many is, he must sleep or die; and the result in many is, that if sleep is finally procured, by persistency in the stimulant and opiate plan, it is the sleep that knows no waking—death. Now there are two distinct and totally diverse conditions of the nervous system produced by immoderate indulgence in alcoholic potations, both attended by delirium of a peculiar character, and therefore both called delirium tremens—a mistake which often leads to the most fatal results.

Now it will be well to inquire, What is the true pathology of delirium tremens, and what are its causes, symptoms, and treatment? Delirium tremens and mania à potu are considered by many as synonymous terms, meaning the same thing, which may or may not be true. Delirium tremens is an indirect debility of the brain and nervous system, produced by constant over-excitement of the organ by any cause whatever. It may be by the long-continued excitement of alcoholic or other stimulants. Their habitual use, especially when persistent, wears out, finally, the excitability of the brain, and it falls into a state of torpor and inactivity incompatible with healthy action, and, if carried beyond a certain point, incompatible with life, and death ensues from exhausted excitability, as expressed by Darwin:—

> "The irritable fibre, goaded to contract,
> By repetition palsied, ceases to act."

But if, as is often the case, from inability of the stomach to retain the liquid fire, or from any other cause, the usual amount of the stimulant being suddenly withdrawn the organ fails to react on the brain through the circulation of the blood, that in turn falls into a state of indirect debility; but as its excitability is not entirely destroyed, a proper season of repose enables it to regain its normal condition, and resume again its former healthy functions. Now, this state of brain and nervous system may be produced by alcohol, or it may result from other causes, as long-continued mental excitement of any kind, as grief, anger, intense application to scientific pursuits, or the direct debility of certain diseases; but from whatever cause produced, it is characterized by the same train of symptoms, and amenable to the same mode of treatment. The symptoms are those of deficient innervation, and are as follows: Surface and extremities pale, cold, and covered with a cold, clammy sweat; face pale and haggard, with wrinkled brow, expressive of fear; pulse small and frequent; pupils small, with tremor of limbs, and with a state of mind which might be expressed by a condition similar to a fearful dream or nightmare. To this state of the system, and to this state alone, should the term delirium tremens be applied. Its pathology having been ascertained, its true treatment follows without the least difficulty. Its first indication is rest—absolute rest, so far as is practicable. The patient should be placed in a room as silent as possible, the stimulus of light and noise excluded; warmth applied to the surface by dry heat, nutritious food liberally supplied; and when these fail, moderate stimulation by aromatic spts. ammonia, or even whiskey and gentle narcotics. Digitalis has succeeded in my hands better than opiates. In most cases of real delirium tremens, the above mode of treatment will generally be successful.

But there is another and far different condition of brain and nervous system, induced by alcoholic stimulants, which is often mistaken for and treated as delirium tremens, and generally with the most fatal results. A man has had a spree; he becomes wakeful, excited, and finally delirious. His physician, having but one idea in his head, and that loosely placed, says delirium tremens, and immediately attacks it with heroic doses of brandy, opium, or morphine, and sagely remarks he must sleep or die, and he redoubles his efforts and finally accomplishes his object of procuring sleep; but it is a stertorous, apoplectic condition that knows no waking. Now let us analyze this case, and see what the trouble was. What were this man's symptoms? We find a young, vigorous man, of full habit, addicted to high living in eating as well as drinking; he has had a spree; his face is flushed; his eye red and watery; skin hot and dry; pulse full and strong; tongue white and dry; pupil small; conjunctiva injected, and delirium, generally of a violent and furious character, with intense head-

* This article is abstracted from the history accompanying a morbid specimen sent to our friend Dr. W. B. Lewis, of this city, for microscopical examination, and is published with the author's consent.

ache. Was this a case of delirium tremens? Can diseases so dissimilar in their character and symptoms, dependent on one and the same condition of brain, nerves, and circulatory system, require the same mode of treatment? Most assuredly not. Now this latter case, instead of being a case of delirium tremens, was one of mania à potu from a congestive state of brain, and required a course of treatment exactly the reverse of the former case. Whilst one would be benefited, as I have before stated, by good feeding, gentle stimulants, and anodynes, the other condition requires bleeding, purging, in a word, a mild or decided antiphlogistic course, according to the severity of the symptoms. With this as with other diseases, it should be treated according to circumstances, and not according to the square rule of Homœopathy, giving the same dose to the tender infant and the robust adult.

Progress of Medical Science.

Inoculability of Tubercle.—The *Lancet* gives the following summary of M. Colin's recent observations on this subject:—M. Colin observes—1. That the fact of the inoculability of tubercle is certainly proved. 2. That in all probability the deposits occurring in the lungs, liver, intestines, and other parts, have a double origin, proceeding partly from the tubercle deposited under the skin, and partly from the processes attended with the formation of pus around the wound; so that in most cases of inoculation there is at once absorption of purulent and of tuberculous matter. 3. The degree and amount of the results of inoculation are proportionate to the quantity of tuberculous matter inserted, and to the intensity of the surrounding inflammation excited, as is best shown in small animals. 4. The tuberculous matter is itself absorbed, and not any supposed virulent material, the absorption being chiefly effected by the lymphatics, through which it is slowly transmitted, and is ultimately deposited in the lung and elsewhere. 5. The pulmonary deposits which result from the inoculation of tubercle are truly tubercular, and occasion no doubt as to their nature when seen as firm semi-transparent granulations. Their nature is, however, less certain when they have become opaque, yellowish, or whitish, in consequence of degeneration or purulent resorption. Insoluble and finely divided foreign bodies, when injected into the veins and conveyed to the lungs, do not produce the same effects as tubercle; they occasion embola without manifest irritation at their periphery, or they become encysted in the centre of minute islets of pneumonic or inflamed lung.

Cure of Acute Orchitis in Twenty-four Hours.—F. Jordan (*British Med. Journal*) thus describes his treatment of a case of acute orchitis:—"A man, aged thirty, had intense pain, intolerable tenderness, and great swelling and induration in both testicles, and could not stand upright. The scrotum was covered with a solution of nitrate of silver (two drachms to the ounce), a stripe of vesication was established over the upper halves of both femoral arteries by means of liniment of iod., and the testicles supported by cotton wool. He was well in twenty-four hours."

The Digestive Powers of Pancreatine.—In the Academy of Sciences of Paris, M. Chauvin and M. Morat have recently read a paper "On the Pancreatic Juice," and the conclusions at which they have arrived are—first, that the general results of their experiments on artificial digestion with this fluid agree with those made by older experimenters, from Eberle to Claude Bernard. Secondly, that in such experiments with artificial digestion, the action of the pancreatic juice is not checked by the presence of gastric juice, nor by hydrochloric acid considerably diluted with water. Thirdly, that at ordinary temperatures, and in inert vessels, the juice does not act so energetically as when maintained at the temperature of the body, and under the influence of the movements of the digestive fluid. Fourthly, in the digestion that ordinarily takes place in the stomach—and this is a capital point—the pancreatic juice preserves its energies intact, notwithstanding the presence of the gastric juice, and may initiate in the interior of the stomach a complete digestion of the three species of alimentary substances. And, lastly, they state that in a clinical point of view they have obtained remarkable results with the aid of pancreatic juice and extract. —*Med. Press and Circular.*

Treatment of Nævus.—Dr. H. Bateman writes as follows to the *Lancet:*—I am desirous of calling attention to a mode of treating nævus which I have now successfully adopted for about fifteen years. It consists in the application of a tartarized antimony plaster to the surface of the tumor, and allowing it to remain until pustules resembling small-pox are produced, and sometimes still larger. The plaster I have used is ordinarily made by having one part of antim. tartarizatum mixed with two parts of melted empl. resinæ, and then spread upon thin leather or linen. It ought to cover the nævus completely, but need not extend beyond it. If it be detached from any cause before it has produced a sufficient amount of inflammation and pustulation it should be renewed immediately. If there be too much inflammation, poultices and fomentations of warm water may be applied. Should the skin be unusually insusceptible, or the nævus unusually thick, equal parts of tartarized antimony and resin plaster may be used.

With comparatively thin nævi the former strength is amply sufficient, and sometimes a single plaster will produce inflammation and pustulation enough to effect a cure. Should the nævus be thicker than usual the stronger plaster may be used.

Antidote of Nicotine.—The deleterious effects of the use of tobacco may be counteracted, if not entirely annihilated, by moistening tobacco, while undergoing the various preparations and fermentations previous to its delivery to the consumer, with a strong infusion or other preparation of water-cresses, since M. Armand has discovered that this vegetable contains principles which, without removing the peculiar aroma of tobacco, destroys the deleterious effects of the alkaloid.—*Chemical News.*

Use of Anæsthetics in Childhood.—Dr. T. Holmes, Surgeon to St. George's Hospital, in London, is not aware of any limitation to the use of anæsthetics in childhood. He has administered them at the earliest period of life, and believes that, with proper care, operations are safer with than without them, even in the the most exhausted and puny infants.

Castanea Vesca in Pertussis.—Dr. Nuziker, of Cincinnati (*Trans. Ill. Med. Society*), has recently published the statement that the infusion of the leaves of the chestnut, drunk freely, is capable of mitigating the severity and greatly lessening the duration of whooping-cough. He makes a simple infusion of the leaves, sweetens it with sugar or syrup, and allows the patient to use it as a drink.

Treatment of Goitre.—Prof. Lucke, of Berne, successfully treats goitre by injections of small doses of strong tincture of iodine.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

Published on the 1st and 15th of each Month, by
WILLIAM WOOD & CO., 61 WALKER STREET, NEW YORK.

FOREIGN AGENCIES.

LONDON—TRÜBNER & CO. | LEIPSIC—B. HERMANN.
PARIS—BOSSANGE ET CIE. | RIO JANEIRO—STEPHENS Y CA.

New York, April 15, 1870.

THE NEW HEALTH LAW.

THE Act to reorganize the local government of the city of New York, which passed the State Legislature April 5th, 1870, embodies some radical changes in the future management of the health department of the Metropolitan Sanitary District. These are comprised in the following provisions:—

"The health department shall consist of the police commissioners of the city of New York, the health officer of the port, and also four officers to be called 'Commissioners of Health of the City of New York,' who shall be appointed by the mayor for a term of five years, two of whom must have been practising physicians in said city for a period of five years preceding their appointment. Said four commissioners of health shall receive an annual salary of five thousand dollars each. These several officers shall together constitute a board, which shall be the head of the health department.

"There shall be four bureaux in this department. The chief officer of one bureau shall be called the 'City Sanitary Inspector,' and he shall be a practising physician of at least ten years in the city of New York. There shall be another bureau, to be called the 'Sanitary Permit Bureau.' There shall be another bureau, to be called the 'Bureau of Street Cleaning.' The chief officer of another bureau shall be called the 'Register of Records.' And in said bureau shall be recorded, without fees, every birth, marriage, and death, and all inquisitions of coroners (excepting those whereby a jury find a death caused by negligence or malicious injury), which shall occur or be taken within the city of New York.

"It shall be the duty of said board, immediately upon organization under this act, to cause to be conformed to this article the code of laws and regulations then or lately adopted by the board of health for the metropolitan sanitary district, which shall be called the 'Sanitary Code.' And said health department is hereby authorized and empowered to add to such sanitary code rom time to time additional provisions for the security of life and health in the city of New York, and therein to distribute appropriate powers and duties to the members and employés of the board of health. Any violation of said code shall be treated and punished as a misdemeanor.

"Whenever, in any law of this State, any power or duty shall be conferred or enjoined upon any board of health, or in relation to the board of health of the metropolitan sanitary district, except as herein provided, the same shall be applicable to the department hereby created."

As can easily be seen, the foregoing is the work of persons who are merely politicians, and not sanitarians. The provisions appear to cover everything and give every indication of the best of intention, but it is to be feared that their practical workings will be very seriously trammelled by non-medical influences. In fact, we cannot see how it can be otherwise with the small minority of medical men in the board. The police commissioners, who can be none other than working politicians, will, with two non-medical commissioners to be appointed by the mayor, make six in all, against three medical men. The medical element, instead of holding the balance of power, as it properly should, is virtually nothing more than advisory, and, judging from the teachings of past experience, every member of the profession knows what that implies.

One of the defects in the Metropolitan Health Bill is also part of the present one, in making the health officer of the port a commissioner. The duties of this functionary are of such a distinct character that his membership of the board is altogether unnecessary, nay hurtful. If he performs his duties properly, he necessarily acts with the board; and if the contrary is the case the said board should be able to call him to account.

The creation of special bureaux, under the jurisdiction of the board, is a feature which, on the whole, is commendable, especially when that for street-cleaning is added. This latter incorporation is a long stride towards enlightened legislation, and if the importance of its enforcement is appreciated by the commission, there will be a splendid opportunity for gaining popular favor. The Metropolitan Health Board never had any such control of the street department, and consequently suffered very much in the estimation for usefulness with those who could not understand the position. They could preach cleanliness, but were powerless to enforce their doctrine. The new board will have the right and privilege, and, if they do not make the most of them, will be held by the community to a proportionally greater accountability. The majority of themedical profession have endorsed the action of the present board, and, with few exceptions, its members have done admirably. The medical commissioners have been gentlemen in whom we have placed confidence, who were competent and conscientious, although much hampered by political chicanery. As a body of medical gen-

tlemen they have, barring a few family quarrels, very faithfully represented medical opinion, and have placed our profession in no unenviable light before the community. In truth, it must be acknowledged that they gave the true character to the board, and were the leaders in almost every scheme for sanitary reform. That they did not accomplish more in that direction is not due to any lack of a right disposition, but to the want of the necessary support from the non-professional members. In the face of this accepted fact, without wishing to prejudge the usefulness of the new board, we dare not expect very much in the way of improving the health of the district. The opinions of three against six are not worth a great deal when the matter comes to a square vote. At all events it must be conceded that the new commission, caparisoned as it is, will have no easy task in even gaining for itself the reputation of the present board, and a still harder one in establishing the necessity for a change. The Metropolitan Board have done well, exceedingly well. Dare we hope that the new health department that is to be will do better?

As the Charter now is, all the appointing power for this department is taken from the hands of the Governor, and placed in those of the Mayor. Any one who has watched the politics of the city is aware that, however just such a change might be on principle, it is absolutely wrong in practice. We assert this notwithstanding the presumption that the new election law is calculated to do away with a great deal of the existing corruption, and that the Charter provides for the reduction of the number of aldermen, and their election on a general ticket. The latter may have the tendency to weaken the pot-house and ward elements, and give the people as a whole a fair opportunity to choose respectable representatives. If our Common Council were really composed of trustworthy men, the Mayor would be as likely to make as good and as appropriate appointments as the Governor.

—Since the above was written, and just before going to press, we learn that the Mayor has made the following appointments for Health Commissioners: Stephen Smith, M.D., Giovanni Ceccarini, M.D., Magnus Gross, and John Mullaly.

Post-mortem sentiment is very well on tombstones or in village newspapers, but we can conceive of nothing more out of place in a medical report than the following sentence, which occurs in the account of a case of ovariotomy performed recently in Columbus, Ohio:

"The patient now withered like a delicate flower under the rays of a scorching sun, after a scathing autumnal frost. The fell destroyer made rapid work, and the patient died at four o'clock A.M."

We are not astonished after this outbreak to be informed that—

"In most cases, and especially in large tumors, it is not only with the greatest uncertainty, but simply impossible to determine certainly the size and character of the pedicle before operating."

It is "with the greatest uncertainty" that the profession can "determine certainly" anything whatever in a case so reported, save that the writer is a "fell destroyer" of the Queen's English.

It is desirable that the next meeting of the American Medical Association will be a success, not only as regards the number in attendance, but in the scientific material that may be presented. Those who may attend, and who may have a desire to profit by such attendance, have a claim on such as may have communications to make: and that is, that the articles shall be reasonably brief and to the point. Let all lengthy papers be presented in abstract, that the time that would otherwise be used in reading them *in extenso* may be devoted to discussion. If this cannot be done by ordinary means, the Association should, in its own interests, compel presumptuous authors to respect the general opinion.

Reviews and Notices of Books.

The Physiology of Man. Designed to represent the existing state of Physiological Science as applied to the functions of the Human Body. By Austin Flint, Jr., M.D., Professor of Physiology and Microscopy in the Bellevue Hospital Medical College, N. Y., etc., etc. Secretion; Excretion; Ductless Glands; Nutrition; Animal Heat; Movements; Voice and Speech. N. Y.: D. Appleton & Co., 1870. 8vo, pp. 516.

This is the third volume of a series of four on the Physiology of Man, which has been promised by our talented and painstaking countryman; and in its general execution, scope and detail of treatment of the subjects considered, it more than equals the well-deserved reputation of its predecessors. The volume as such, while it is complete in itself, is after all only a part of a grand whole, which is to be finished by the fourth volume. Some of the subjects treated of in the present work have an especial interest to the advanced student of physiology, from the fact that they contain for the first time, embodied in a permanent form, many original observations of our author, prominent among which must be mentioned those bearing upon a new excretory function of the liver and upon the mechanism of glycogenesis. A delay in the reception of the work compels us, in the interest of our readers, to pass it by with a hasty reference to its general merits, rather than by a still longer delay to give it that extended review which its intrinsic worth demands.

A Practical Treatise on the Diseases of Children. By J. Forsyth Meigs, M.D., and William Pepper, M.D. Fourth edition, revised and greatly enlarged. Philadelphia: Lindsay & Blakiston. 1870.

Good books on the diseases of children are so scarce that we cordially welcome this new edition of the once popular work of Dr. Meigs. The labor of revision was found to involve so many changes, and the addition of so much new material, that Dr. Meigs called to his assistance Dr. William Pepper, a gentleman of large experience, and well qualified for the task. The result of their joint labors is now presented to the public, and so great have been the changes that the volume before us has really the interest of a new book. Several of the articles have been much enlarged, es-

pecially those on convulsions, croup, tracheotomy, chorea, thrush, and parasitic diseases of the skin. The articles on diseases of the stomach and intestines, and upon eczematous affections, have been either re-written or entirely re-arranged. In the old editions the consideration of several important subjects was altogether omitted; that defect has been supplied in the present volume by seventeen new articles, treating, in an exhaustive manner, of the diseases of the heart, including cyanosis, chronic hydrocephalus, tetanus, and atrophic infantile paralysis; rheumatism, mumps, rickets, tuberculosis, and infantile syphilis; typhoid fever, etc., etc. On these and other topics the most recent opinions of eminent foreign and American authorities are impartially reviewed, and compared with the results of the author's observations and experience.

The general plan of the original work has been preserved, and probably nothing more clear and convenient could have been substituted for it. The introductory essay on the clinical examination of children gives much valuable information in small compass. The diseases are divided into eight classes, and each class is subdivided into sections. Class I. treats of diseases of the respiratory organs. Class II. is devoted to disorders of the organs of circulation. Under Class III. we find a systematic consideration of the diseases of the digestive organs, taken in order, from the mouth and stomach to the intestines. Diseases of the nervous system find their place in Class IV. Class V. includes constitutional diseases. The eruptive fevers constitute Class VI. Diseases of the skin are treated of in five chapters, under Class VII.; and Class VIII. disposes of the subject of worms in the alimentary canal.

The portion of each chapter devoted to treatment, and the discussion of therapeutic measures, is remarkably large and satisfactory. In this department many radical changes are conspicuous. The authors have entirely abandoned the use of calomel, for instance, in membranous croup, pneumonia, pleurisy, and all other diseases excepting congenital syphilis. In regard to this disease they say: "If the previous children of a mother have proved syphilitic, it is well to subject her to a mild mercurial course during her pregnancy." The use of venesection is advised as a rule in the early stage of acute pleurisy, in simple meningitis, and in vigorous subjects in eclampsia. It is also admitted in exceptional cases of spasmodic and membranous croup, pneumonia, pertussis, and, more rarely, in rubeola. But the opinions expressed in former editions on bleeding and calomel are explicitly retracted, and the more recent opinions are fortified by abundant statistics accumulated in the course of many years' additional experience.

A pretty free use of alcoholic stimulants is advised under certain circumstances, but only when there are undoubted signs of debility, and it is necessary to aid or sustain the vital forces. In this respect the views of the authors do not differ materially from those of a large majority of physicians both in this country and in Europe.

We think it greatly in favor of the volume before us that it is written in an easy, pleasant, and perspicuous style. Too many authors who have really valuable information to impart do not pay sufficient attention to the manner in which they express their views. We are rather surprised, however, in the present case, to find both ungrammatical and awkward expressions in the preface, while in the body of the work there is so little to find fault with. It is not in very good taste, either, to speak of the "kind favor" with which the former editions were received by the profession. Nobody buys a medical book as a "kind favor," nor ought any author to expect such kindness. Medical men buy books because they expect to learn something from them, and not for the purpose of obliging the writer or publisher. We can say nothing more favorable of the new book on diseases of children than that it may be safely purchased on its own merits.

THE PATHOLOGY AND TREATMENT OF STRICTURE OF THE URETHRA AND URINARY FISTULA.—BY SIR HENRY THOMPSON, F.R.C.S., etc. From the third and revised London edition, 8vo., pp. 359. Philadelphia: Henry C. Lea. 1869.

IT is somewhat difficult to speak in proper terms of this standard work of Sir Henry Thompson, for to those familiar with the former editions, nothing beyond the announcement of a new and revised edition can be necessary: to those who have yet to make its acquaintance, a just description would seem extravagant praise.

Originally published in 1854, when the Jacksonian Prize of the Royal College of Surgeons was awarded to it, it has been the chief means of making the author the highest living authority on the subject of which it treats. Indeed, his views upon all points connected with the pathology and treatment of stricture, are so familiar that discussion is unnecessary; it only remains to indicate the changes that increased experience has led the author to make in his work. In his preface these are distinctly stated. Instead of increasing the size of the volume, it has been materially reduced, partly by removing controversial matter regarding subjects upon which the profession is now agreed, and partly by dropping all the "illustrative cases," which are no longer required to justify the statements of so distinguished an authority.

Such additions as have been made to the work are mainly condensed from the author's recent "Clinical Lectures on Diseases of the Urinary Organs," which were reviewed in this journal last May. These, in brief, may be summed up as the substitution of flexible for metallic instruments in the dilatation of strictures—a revocation of all the author's previous views on this point; a consideration of the value of Endoscopy, of which the author has not a very high opinion, having "never yet found it of the slightest service in stricture;" the even distension of strictures by the author's dilator, instead of their rupture, as proposed by Mr. Holt; and a few additional suggestions concerning the therapeutical treatment of stricture.

The present edition, like its predecessors, is divided into twelve chapters, treating successively of the anatomy and physiology of the urethra, the pathology, pathological effects and causes of stricture, its diagnosis, and its treatment by dilatation, chemical agents, internal and external incisions; of retention of urine, depending on stricture, of urinary abscess and fistula, and, lastly, of stricture of the female urethra.

The mere fact of a work of this kind having reached its third edition may be said to place it beyond the reach of either censure or praise. But, as we have long regarded it as perhaps the ablest and most perfect monograph in the English language, we have re-read it with care from beginning to end; and it is simple justice to say that no one can do this without admiration of the author's learning, accuracy of detail, and extraordinary capacity for imparting information. The American edition is excellently printed and illustrated.

A PHYSICIAN'S PROBLEMS. By CHARLES ELAM, M.D., M.B.C.P. Boston: Fields, Osgood & Co. 12mo., pp. 400.

THE natural and moral diversities of individuals and races, and the laws which govern innate qualities, moral and intellectual, are subjects of practical interest to the

physician. In this work Dr. Elam attempts their investigation. It is thoughtfully and suggestively written, and calculated to direct intelligent inquiry concerning complex problems which some of the best minds are studying. One of the purposes of the author is to indicate the origin and mode of perpetuation of those varieties of organization, intelligence, and general tendencies towards vice or virtue, which seem to be so capriciously allotted to families, and to the human race generally. The chapters On Natural Heritage, and On Degenerations in Man, should especially attract attention, treating of subjects but little understood, and peculiarly regarding man as an individual and when aggregated in communities. Those on Moral and Criminal Epidemics, Illusions and Hallucinations, Somnambulism, and Revery and Abstraction, are full of interesting matter pleasantly imparted. Dr. Elam's "Problems" are well worthy of a wide circulation.

VITAL RESOURCES, or How to Become Physiologically Younger and Stronger. By JEROME KIDDER, M.D. New York: Published by the Author.

THE object of this little book, the author tells us in the preface, is "The setting forth that man is endowed with the possession of a plurality of personality." But for this announcement, the reader would never suspect the work to be anything more than a very feeble attempt to extol the virtues of electricity, of which the author eloquently asks: "Indeed, if the kind of undulations or vibrations of the ether, or of particles of matter producing what we call heat, can arouse the latent vitality of an egg till it spreads its wings in the aërial regions, a bird, why cannot electricity, under favorable conditions, arouse a latent inherited personality of an individual so as to give additional vigor, both of the body and the mind?" Unfortunately we are not "endowed with the possession" of powers sufficiently vigorous to grapple with this conundrum.

PHOTOGRAPHS OF DISEASES OF THE SKIN. Taken from Life, under the superintendence of HOWARD F. DAMON, M.D. With letter-press descriptions. Boston: James Campbell, 18 Tremont Street. 1870.

THIS admirable series of photographs, to which we have previously alluded, is now complete, and consists of twenty-four views, including typical cases of the principal cutaneous diseases. The selection of these cases has been made by Dr. Damon from several thousands, and the greatest pains have been taken to render each view, as a work of art, as nearly perfect as possible. No attempt has been made to represent the color, but the simple photograph, sharply defined, is preferable for purposes of study to anything but the most expensive colored drawings. These views are so clear that they will bear magnifying to life size with an ordinary lens. There would be more satisfaction, however, in examining them thus magnified, if the texture of the paper were less conspicuous. This defect the artist could probably remedy. Each photograph is accompanied by a letter-press description of the case, and the whole is contained in a neat portfolio.

REDUCTION OF DISLOCATIONS. By WILLIAM WARREN GREENE, M.D., Professor of Surgery in the Medical School of Maine, etc., etc.

THIS is a little pamphlet devoted to the consideration of the principal obstacles encountered in the reduction of dislocations, and the most appropriate treatment of these injuries. Professor Greene is of opinion—

I. That the main opposing force to the reduction of dislocations is the untorn portion of the capsular ligament.

II. That in our efforts at reduction the primary object should be the relaxation of the untorn portion of this ligament, and that whatever mode of procedure accomplishes this with most facility is the best.

III. That occasionally the small size or peculiar shape of the rent in the capsule, or, in peculiar conditions of the nervous system, muscular contractions, may constitute the major forces with which we have to deal; but that these cases are so extremely rare as not at all to invalidate the general rule.

The arguments of Professor Greene in support of these views, based as they are upon an extensive surgical experience, extending over a period of fourteen years, are well worthy the attention of the profession.

ON THE PHYSICAL BASIS OF LIFE. By T. H. HUXLEY, LL.D, F.R.S. No. 1. University Series. New Haven, Conn.: Charles C. Hatfield. 1870. Price 25 cents.

THE University Series, of which this is the first number, will consist of scientific and educational essays by the ablest men of Europe and America. The publisher announces his intention of making a selection that will be worthy of the careful thought of every educated person in the country. Professor Huxley's celebrated essay on "Protoplasm," or the Physical Basis of Life, cannot be too widely known, and if it is a fair specimen of the series they will soon become popular.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MARCH 23, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

THROMBOSIS OF PORTAL VEIN.

DR. JANEWAY presented a specimen of thrombosis of the portal vein taken from a man forty-seven years of age, who was admitted into Charity Hospital, June 16, 1869. He stated that in 1861 he had evidences of phthisis, in the shape of hæmoptysis, cough, profuse night sweats, and emaciation; that after a time these disappeared and he regained his flesh and strength; and that in 1867 these symptoms again occurred, and again in the course of time disappeared. In January, 1868, he was attacked with acute articular rheumatism, and it was not until September of the following year that it disappeared. Two weeks prior to admission he was again seized with rheumatism, for which he entered the hospital. Under the alkaline treatment improvement was marked and rapid, but on the 30th of June he suffered a relapse. This continued until the latter part of July, and on July 5th there was superadded diarrhœa and abdominal pain. In the early part of August ascites developed, and the liver is noted as reduced in size. On the 8th of August the distension was very great, with splenic enlargement and abdominal pain. Under the use of bi-tart. pot. the ascites disappeared. The latter part of September he was well enough to be a helper around the ward. No further notice was taken of his case until March 11th, when he was seized with chilly feelings, followed by fever, increased frequency of the pulse, and dry tongue. This, with dry tongue and constipated bowels, lasted for two days, when jaundice occurred, accompanied with splenic enlargement and pain on pressure. The abdomen contained a slight amount. Dr. Janeway saw him on the 17th, and found him jaundiced, with tongue dry, somewhat stupid, with normal pulse and normal skin. The right side of the thorax was retracted considerably; there was dulness on percussion over the right lung,

especially in its upper portion, with coarse and fine râles. The diagnosis of thrombosis of the portal vein was made, and also fibrous induration of the lung.

AUTOPSY.

The brain and larynx were not examined. The right lung was firmly adherent to the thoracic wall. The upper lobe of the right lung was the seat of fibrous induration with the attendant dilatation of the bronchi, and there was in this situation, besides, a small cavity surrounded by cheesy pneumonia. In the left lung were marked evidences of chronic bronchitis. The liver had its surface somewhat wrinkled, and its left lobe was considerably enlarged at the expense of the right. The whole organ was somewhat fatty. The spleen was of a deep blackish color, and weighed four pounds.

On opening the portal vein there was found occluding it a thrombus. This commenced by a tapering extremity at the junction of the superior mesenteric and splenic, and after extending for half an inch it occupied the whole vein, with the exception of a channel capable of admitting a small probe. The thrombus almost filled the vein as far as the bifurcation of the portal into right and left branches, in the latter of which it tapered to a considerable distance. The small branches were perfectly free from clot. The thrombus was firm, and of a reddish-grey color. In the middle coat of the splenic vein was a calcareous plate, about two inches in length, projecting into the calibre of the vessel sufficiently far to present some obstruction to the current of blood. Besides this the artery near the point of bifurcation contained a calcareous degeneration. Dr. Janeway was disposed to think that this thrombosis had been due to the obstructions referred to, and had possibly commenced when the patient first showed the signs of ascites. The kidneys were fatty. The intestinal mucous membrane was pale, and was coated with a large amount of mucus.

FIBRO-MYOMA UTERI, TREATED BY ELECTROLYSIS.

Dr. Neftel exhibited a fibro-myoma of the uterus, with the following history:—

Mrs. G., ætat. 42, mother of two children. After the birth of her last child, eight years ago, she has never recovered her former health, suffering from uterine troubles, dyspepsia, and pain in the lower part of the abdomen; the uterus continually increasing in size. Her menstruation became profuse, and caused a high degree of anæmia. She has been treated by different physicians, the diagnosis being hypertrophy of the womb. Last fall she came under the care of Dr. Sims, who made the following diagnosis: Fibroid tumor of the posterior wall of the uterus protruding into the uterine cavity; the uterus very much enlarged (the size of a man's head), felt through the abdominal wall as a solid tumor extending two inches above the umbilicus. The patient, of a delicate constitution, was suffering from intense uterine pains; her menstruation was profuse, her digestion impaired. Dr. Sims, after having treated the patient for several months without any noticeable change, proposed to me to try with him the electrolytic treatment of the tumor, and January 3, 1870, the first electrolytic operation was performed. Having placed the patient on the left side, the neck of the womb was brought in view by means of Sims' speculum. The cathode in the shape of a needle 12 inches long was introduced by Dr. Sims into the tumor; nine inches entering it through the posterior wall of the uterine cavity, the remaining part of the needle being carefully isolated. The anode—a broad plate—was applied to the skin near the hip. The current, beginning with two Siemens' elements, was gradually and insensibly increased to 15 elements during 11 minutes. The pain was considerable, and increased after the operation; but no febrile symptoms followed. The husband of the patient, who himself has studied medicine, repeatedly made very exact thermometrical observations with Geissler's instrument, and found after the operation the temperature one degree (Fahrenheit) below the normal, which must be attributed to the extreme anæmia of the patient. About a fortnight after the first electrolytic application, Dr. Sims found the tumor considerably smaller and softer. The second electrolytic application was made in the same way January 31, using 22 Siemens' elements during 10 minutes. February 21, the patient's husband wrote to me: "Dr. Sims has just left us, and he says that the tumor is less in size and more soft, so that he is amazed." Feb. 22, the third electrolytic application was made with 30 elements during 15 minutes; and March 2, the fourth application with 25 elements, 15 minutes. As it was, however, supposed that the tumor protruded into the uterine cavity, we proposed to use the next time, instead of a needle, a metallic sound, which should be isolated on the side towards the uterine wall, and should be brought into contact only with the supposed surface of the tumor. In this way we expected to attack from without the tumor that was already undergoing a regressive metamorphosis from within. Accordingly the fifth application was made March 9, with 25 elements during 15 minutes. The pain was severe, and increased afterwards. I have not seen the patient since, but Dr. Sims informed me that contractions of the uterus were felt after the last application. On the 14th March, the patient having exposed herself to a cold, symptoms of peritonitis set in, followed by a sudden collapse, ending in her death the next day.

I am greatly indebted to the enlightened and philanthropic gentleman—the husband of the deceased—for the permission to make a post-mortem examination of the abdominal cavity and of the uterus. The facts revealed by it are of the utmost scientific and practical importance, and will contribute to save many sufferers from a hitherto intractable diseased condition. I made the post-mortem examination in the presence and with the kind assistance of Drs. Sims, Metcalfe, Nott, and Greene, of Boston.

On opening the abdomen, the uterus presented itself anteflected, enlarged, the fundus not reaching the umbilicus within an inch. The serous membrane of normal appearance, without any adhesions; and about a tumbler of sero-purulent matter, not containing fibrine, was found in the abdominal cavity. A probe introduced into the uterine cavity proved that the anterior wall of the uterus was not much thickened,—perhaps as much as in the latter part of pregnancy. The large size of the uterus was almost entirely owing to its posterior wall and to the fundus. The fundus uteri above the uterine canal was thicker than the length of the canal itself, the latter being 6½ inches. On touching the posterior wall of the organ, and especially the fundus uteri, fluctuation was felt, and pus was suspected. On opening the uterine canal through its anterior wall, its calibre was found almost of normal size, and its length not reaching the middle of the tumor. Cutting through the posterior wall of the uterine cavity a large fibro-myoma was found situated in the lower part of the wall, and two small separate fibro-myomatous masses much higher. But these fibro-myomata constituted only one-fourth of the tumor, three parts of which presented the following remarkable transformation: a clear, slightly yellowish fluid, much resembling synovia, filling irregular spaces

formed by a material evidently undergoing the same metamorphosis. The microscopical examination showed that the solid tumor was a so-called myoma, or rather fibro-myoma of Virchow (generally improperly called fibroid or fibrous tumor). It consists of smooth (organic) muscular fibres, and connective tissue; consequently of the same histological elements as the normal structure of the uterus itself. The softened part of the tumor contained, besides the amorphous transparent fluid, the histological elements of the tumor in the different degrees of regressive metamorphosis. There was no pus, nor any other products of inflammation; it was simply the tumor itself undergoing liquefaction and absorption. I examined the fluid chemically, and found that it contained alkali, albuminates, and mucin. That this fluid has not existed in the tumor before the electrolytic treatment is proved by the examination of Dr. Sims. This experienced gynæcologist found the whole tumor exceedingly *hard* before the electrolysis, and quite soft and fluctuating after it,—just as we discovered it post-mortem.

The walls of the uterus are hypertrophied as in pregnancy, and its vessels larger and more numerous. The right Fallopian tube contained muco-purulent matter. The tumor was situated within the posterior wall and within the fundus, but was not protruding into the uterine cavity. It was, therefore, the variety which Sir James Simpson * calls the intramural, and Virchow † the intraparietal myoma. An intramural tumor of such a magnitude could only be removed together with the whole uterus, and no other surgical operation could have accomplished it. This case showed me for the first time anatomically what I have so often observed clinically during the electrolytic treatment of tumors. They can be felt becoming soft, elastic, fluctuating, diminishing in size until they entirely disappear. The same would have undoubtedly taken place with this myomatous tumor, had it been left to itself after the fourth electrolytic application, or even after the third; or had not the fatal peritonitis set in. This latter I am yet unable to explain. I have never observed inflammation to follow the electrolytic treatment; at least exact thermometrical observations have never shown an increased temperature after electrolysis. I do not even think that the unnecessary application to the mucous membrane of the uterus could have alone produced inflammation, because in strictures of the urethra I have repeatedly treated the mucous membrane electrolytically with happy results, and never produced inflammation. In the present case the peritonitis appeared only after the patient had exposed herself to a cold, and possibly some epidemic influence may be taken into consideration, as at the same time I have heard of several other women attacked with peritonitis. From the anatomical examination of this case I am convinced that intramural tumors of the uterus, inaccessible to a surgical operation except the dangerous removal of the whole organ, can be successfully treated by electrolysis.

THE DIAGNOSIS OF ABDOMINAL TUMORS.

Dr. Loomis, in view of the difficulty that not unfrequently occurs in making a correct differential diagnosis between solid and fluid tumors in the abdomen, thought that Dr. Sims might have been mistaken as to the true character of the growth in the first place; in other words, there was a possibility of its being fluid from the start.

Dr. Neftel replied that the patient was much emaciated, the tumor was large, and the abdominal walls were very thin; and the case, as a whole, presented no unusual difficulties to one who was not even an expert. Again, the change in the consistency of the growth took place in a very short time after the treatment by electrolysis commenced.

SYMPATHETIC OPHTHALMIA.

Dr. H. Knapp exhibited an eye which had been extirpated by Dr. Thomas Pooley for causing sympathetic ophthalmia in its fellow. The specimen presented a scar through the corneo-scleral juncture, in which the peripheral part of the iris was firmly caught. Iris, ciliary processes, and the whole choroid were saturated with lymphoid cells—the former uniformly, the choroid in circumscribed spaces. The ciliary muscle and retina were unaffected. Through the vitreous body were scattered lymphoid cells, and finely anastomosing stellate cells. The ciliary nerves running through the supra-choroid layer, between the scar and the posterior pole of the globe, were perfectly normal.

The specimen, therefore, illustrated the anatomical conditions of *exudative iridochoroiditis*. It is not possible to say whether this kind of inflammation, or the compression of the nerves of the iris in the contracting scar, induced the affection of the other eye.

FIBROID OF UTERUS, ETC.

Dr. Peugnet presented a uterus and annexa removed from a patient, with the following history:—

March 3*d*, 1863. Mrs. T., æt. 31. Married. Has had only one child, now 7 years of age. Suffering for several years past from severe dysmenorrhœa, with considerable disturbance of general health in consequence. Uterus in normal position; cervix rather elongated; Simpson's sound cannot be introduced more than an inch; a probe but little further; introducing finger in rectum and depressing uterus by means of a sound introduced in bladder conveys a feeling of a hard resisting nodule just behind cervix; diagnosis, a fibroid in posterior wall of uterus. Introduced a small sponge tent, which was removed next day.

March 7*th*. A larger sponge tent introduced.

March 23*d*. A third and good-sized one was introduced.

March 26*th*. The cervical canal sufficiently dilated to permit introduction of end of finger, when the fibroid could be distinctly felt just beyond os internum. Simpson's sound passed without difficulty to fundus; entered about three inches. Dysmenorrhœic symptoms very much diminished at next menstrual period, which occurred on the 30th of March. General health improved steadily, and no necessity for further treatment until

August 14*th*, 1867, the menstrual flow being excessive, the prostration therefrom necessitated the introduction of a tampon, which had to be renewed daily until the 1st of September. She remained in a very anæmic condition for some time afterward.

October 25*th*, 1869. Her husband came to the city with her, and requested me to accompany her to Dr. Thomas, whom she had been advised to consult. She had recently noticed a large lump on left side, accompanied with considerable tenderness, which had come on suddenly at menstrual period in August. Menstrual flow had been rather scanty for the few preceding periods. On examination we found a large tumor in left ilio-pubic region, which had produced right latero-version. Conjoined palpation between vaginal cul-de-sac and abdomen conveys a semi-fluctuating sensation. Finger in rectum a similar sensation. Tumor immovable. The posterior lip of uterus presents a peculiar elongated appearance; os externum dilated; the fibroid

* Sir James Simpson Obstetric Memoirs, Vol. I. p. 117.
† Virchow, Die krankhaften Geschwülste, Bd. III. p. 116.

could be distinctly seen in posterior wall. In order to explore uterus, the probe had to be flexed to about the section of a 4-inch circle; it was then passed to fundus without difficulty, the length of cavity being about 3 inches. The Doctor was unwilling to make a positive diagnosis, but thought that it was probably an hæmatocele produced by the regurgitation of menstrual flow through the Fallopian tube, owing to the obstruction by fibroid.

Oct. 25th. Saw her again with Dr. Thomas. She had menstruated as usual on the 1st instant. Tumor apparently about the same size; a slight increase of tenderness; complains of considerable pain across lower portion of abdomen; conjoined examination presents same result as previous one. The Doctor and I now concluded that it was a fibroid in which an inflammatory action was going on. Advised patient to let it alone.

Feb. 7th, 1870. Called to see the case in consultation with Dr. Sprague. The patient, after an interval of nine weeks, commenced menstruating freely on the 30th of January; the flow was increasing in quantity; pulse 98 and thready; advised the Doctor, if it did not diminish materially before morning, to apply tampon, in order to avoid a recurrence of a prostration similar to the one which occurred in August, 1867.

Feb. 10th. The flows till persisting. The Doctor having been called away, I removed tampon and applied another one, having previously applied persulphate of iron to cervix.

Feb. 12th. Hemorrhage still persisting; patient becoming more prostrated; on examination with speculum found cervix very much tumefied, blood flowing freely from cavity of uterus; threw in an injection of ½ of persulphate of iron to ½ of glycerine and starch ointment, by means of Lente's syringe; then applied tampon of cotton saturated with sol. carbolic acid in olive oil; patient taken with syncope immediately after, and did not rally for some time.

Feb. 6th, P.M. Pulse 124, hard; respiration 20; considerable tenderness in lower part of abdomen. Hypodermic injection of morphine to be repeated as often as necessary.

Feb. 15th, A.M. Has had complete suppression of urine for preceding 12 hours; taken with vomiting a black and offensive fluid; pulse 130; a peculiar odor emanates from body, but no discharge whatsoever.

Feb. 16th. Gradually sinking; unconscious since six P.M. last night; died at about noon.

The autopsy was made by Dr. Sprague. Few slight adhesions in upper portion of peritoneal cavity, and in the lower abdominal and pelvic cavities. Tumor in the ilio-pubic region, which apparently contained fluid and was adherent to the pelvic fascia; this was removed with the uterus and rectum, but broke as it was being conveyed home, discharging a large quantity of red-colored and intensely fetid fluid. There were evidences of metritis; a fibroid was distinctly seen in the posterior wall of the uterus, and was found to contain ten ounces of fluid, which, under the microscope, was made up mostly of blood corpuscles.

COMPLICATIONS OF RELAPSING FEVER.

Dr. C. C. Lee presented specimens illustrating some of the results of the more fatal complications of relapsing fever. They were taken from the body of a woman admitted to Charity Hospital on the 14th of February, in the seventh month of her ninth pregnancy. Her previous pregnancies presented no complications, and she was in good health at the time referred to, having entered the hospital for the sake of being confined. The obstetric ward undergoing repairs, she was placed temporarily in one of the medical wards. Shortly after there occurred three cases of relapsing fever in this apartment, and the patient took it. On the fourth day after the attack she aborted and gave birth to a feeble child, which lived only thirty-six hours. The placenta was expelled ten minutes after the child was born, and Dr. Williams, who examined the organ, thought it complete and entire, with the membranes. A considerable amount of blood having been lost, more nourishing food and an increase in the amount of tonics were necessary. She went on with very slight change for the worse until the fourth day succeeding, when she was seized during the preceding night with a well-marked chill, followed by lancinating pains in chest, increased frequency of respiration, and increased temperature. On examination of her chest pneumonia was discovered, limited to the upper and middle portions of right lung. The vomiting recurred coincidently with the pneumonia, and the patient's strength ran down very rapidly. The same treatment was continued, together with turpentine stupes and oil silk to the chest, and tr. aconite in three-drop doses every three hours, until the pulse was reduced from 156 to 130. Beyond that point it was not thought wise to push the remedy. The loss of blood which she sustained at her miscarriage, the inability to take food which was marked throughout, the recurrence of nausea and vomiting, all conspired to make the case an exceedingly grave one from the first, and the patient, in spite of the most careful treatment, slowly sank. The pneumonia spread until the whole right lung became solidified, the left remaining intact. No pleuritic complication showed itself until the second day before death. The highest run of temperature was 104, which was the day after the pneumonia made its appearance. The administration of the aconite did not affect the temperature a particle. The patient died on the twelfth day after the appearance of the pneumonia, the sixteenth day after the miscarriage, and the nineteenth after the first symptoms of relapsing fever.

The body was examined thirteen hours after death. All the abdominal organs were found healthy except the stomach, which was markedly congested, and the spleen, which was slightly enlarged. A mass was discovered in the upper portion of the cavity of the uterus near the fundus, which looked very much like retained placenta; but on careful microscopic examination by Dr. W. B. Lewis, proved to be a fibro-polypoid, which had doubtless existed before pregnancy began. The right lung was solidified, with the exception of a small portion of the anterior surface. Recent pleuritic effusion was noticeable in upper portion of same lung.

In regard to the specimen of the uterus, he thought it had a good deal of medico-legal value, because if such a growth were found on post-mortem examination in a case of supposed abortion, the suspicion of placental retention would be very strong. In view of its importance, he moved its reference to the committee on microscopy.

EXTENSIVE PERICARDITIS.

A second specimen by Dr. Lee showed very extensive pericarditis. It was taken from the body of a man sixty-eight years of age. He entered the medical wards of Charity Hospital on Saturday night last. He had pneumonia extending over the whole of the right lung, complicated with slight pleurisy. The latter increased very rapidly; and, being extremely exhausted by previous exposure, he rapidly sank, and died in the course of twenty-four hours. Death was the result partly of the pneumonic condition, partly of previous exposure, and partly of the weakened condition

of the heart; the pericardium being not only extensively adherent, but containing twelve ounces of fluid.

UTERINE FIBROID.

Dr. Cutter exhibited a uterine fibroid which he had enucleated that afternoon from a German lady thirty-five years of age, married, but childless. From the earliest period of her maidenhood she complained of painful menstruation. Dr. C. saw her about three months ago, at the request of Dr. ——. She had previously consulted Dr. Emmet, who diagnosticated a uterine tumor, the nature and precise situation of which he could not ascertain without dilating the os. Dr. C. introduced a sponge tent and found the tumor, but was unable to determine its character. Shortly after this she had one of her monthly periods, during which she bled very profusely. Just before he expected the next period the uterine canal was dilated, and when the catamenia made its appearance he applied persulphate of iron to the cervix, and introduced a cotton tampon. The result was most gratifying. In her subsequent periods the hemorrhage was inconsiderable, but she did not recover from the effects of the bleeding three months before until just before the operation.

The operation was commenced by introducing Nott's speculum. With the assistance of Drs. Krackowizer and Kammerer he incised the neck on either side and posteriorly, but was compelled to do the same to the anterior lip before he could remove the growth. It was detached by the finger, and found to spring from the anterior uterine wall. The patient was doing well at the time of the report.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 7, 1870.

Dr. George T. Elliot, President, in the Chair.

PROGNOSIS IN CHRONIC DISEASE OF THE HEART.

(Continued from page 69.)

Dr. Metcalfe remarked that Dr. Flint's paper had almost exhausted the subject (though by no means the audience), and left little to say except by way of assent and confirmation. But a matter of so great importance would justify some degree of iteration.

It was of the utmost consequence to secure accuracy in diagnosis; and too many of our statistics of the results of heart-diseases were rendered valueless from ignorance or carelessness in regard to this point. Most physicians in their early practice would be sure to fall into errors. He had himself, when he began teaching, been certain of a great many things which he was now convinced that he neither then knew nor had since acquired. A single examination was rarely sufficient to determine the morbid condition beyond a doubt. The patient must be seen under a great variety of circumstances; and care must be taken to eliminate such sources of error as, for instance, the spanæmia of pregnancy and lactation, or the three *isms* of which he used to speak to his class,—the nicotism, the rheumatism, and the onanism.

Supposing the diagnosis accurate, the consideration of idiosyncrasy should enter as an important element into the prognosis,—the fact that, with apparently the same lesion, one man might live forty years, and another die in as many days. That sudden death from heart-disease was very rare, he was fully convinced. It was the suddenness of a fatal event that patients were most in dread of; and if they could only be disabused of this idea, their disease would be disarmed of its chief terrors. Ten years ago he had come in charge of a patient whose former physician had diagnosticated extensive lesions of the heart, with atheroma of the aorta. The man was in a state of mortal apprehension; had given up his business; never left the house without an attendant to watch him; and then his wife would be in an agony of suspense till his return. The speaker had recognized the serious condition of the heart, and told the patient: "You have heart-disease, and I cannot say when you are likely to die; but you are not likely to die suddenly, and my advice is to dismiss your watchman, and go about your business." The patient had followed his counsel, was still at his business, and was getting along very comfortably, though of course nearer death than ten years ago.

Perhaps the most important of the complications affecting prognosis was renal disease. He knew a gay youth of some sixty summers who had contracted a cardiac affection from rheumatism forty years ago. But his kidneys were in excellent order, and his long-continued good condition was doubtless referable to the cause insisted upon by Dr. Flint,—the power of healthy blood to maintain healthy nutrition, despite considerable derangement of the central organ of circulation.

The Doctor related cases bearing upon the subject of angina pectoris, referred to in the paper. A lady whom he had found almost pulseless from this affection, ten years ago, was still alive and doing well. A man whose pulse had once fallen to thirty, and even to twenty-three in the minute, was likely to last a good while yet. A lady, seven years ago, received a blow on the head, which was followed by pneumonia. Her pulse went down to thirty. Mitral disease was diagnosticated; but she recovered, and last year had another attack of pneumonia, during which the pulse and respiration were each thirty. By April she was convalescent, and had since been very well. Two young ladies, in whose cases his diagnosis of heart-trouble was confirmed by Drs. Swett and Clark, had since married and borne children, and were in a state of health fairly enviable.

The President hoped that some gentleman would allude to the occasional disappearance of well-marked organic disease of the heart, and the possible clashing of diagnoses which might result. He thought the life-insurance tables, as a rule, bore too hard upon heart-disease.

Dr. Metcalfe replied that this consideration made yet more evident the necessity of repeated examinations. He could recall many cases where murmurs had existed and then disappeared for a long time, the autopsy finally showing organic lesion. As a life-insurance examiner he had made it a point, whenever there was anything wrong in the rhythm or sounds of the heart, never to be satisfied until he had interrogated them under many different conditions. But it was just as important to interrogate the kidneys. He had seen many patients examined for days and days to ascertain the state of the heart, when that of the kidneys was not at all investigated. Only this morning an insurance document had been shown him with the instruction: "*If the policy exceed twenty thousand dollars*, examine the state of the urine!"

Dr. Bibbins, speaking of calcification of the heart in the aged, said that for the fourteen years during which he had been physician to the Twentieth Street Asylum for Old Ladies,—none of them admitted under sixty years of age, and some of them living to ninety,—there had not been a single case where heart-disease had caused sudden death. Such patients died of dropsy or other more or less protracted illness.

Dr. Neftel closed the discussion, referring especially

to the effect upon the heart of disorder of the vaso-motor nerves, and to angina pectoris as produced by an abnormal condition of the cervical sympathetic.

The Society adjourned.

Medical Items and News.

The Woman's Medical College of the New York Infirmary held its first Commencement on the 2d inst., at the Hall of the Young Men's Christian Association. The President, Samuel Willetts, Esq., with a few appropriate remarks, conferred the degree of M.D. upon Miss Eliza B. Phelps, of Iowa, and certificates of having successfully passed their final examination upon Misses Celestia A. Loring, of Massachusetts, Ellen E. Mitchell, of Pennsylvania, Laura Morgan, of New York, and Emma C. Ward, of New Jersey,—who will not have completed the requisite three years' study until June next, when they are to receive their diplomas. The final examinations are conducted by a Board of eight Professors, selected from the Faculties of the College of Physicians and Surgeons, the University Medical College, and the Bellevue Hospital Medical College. Prof. McCready, in behalf of this Board, stated as its unanimous verdict, that the class had passed the severe examination most satisfactorily, and shown a proficiency decidedly beyond that of the average of the male candidates for graduation. Prof. Emily Blackwell, M.D., gave an address eminently clear and practical, exhorting the students not to allow their exclusion from medical societies and other opportunities open to male graduates, to cool their professional ardor or prevent their maintaining the true professional spirit. Remarks were made by Rev. Geo. H. Hepworth and Dr. I. I. Hayes; and the exercises closed with the Valedictory, well delivered by Miss Morgan. The Spring Course of this College opened on the 11th inst., to continue nine weeks.

The Order of Leopold Conferred.—The Knighthood of this Order has been conferred on Dr. Oppolzer, of Vienna.

The Health of Von Graefe.—This renowned oculist has returned from Italy to Berlin with improved health.

Successful Extirpation of One Kidney.—Simon, of Heidelberg, recently extirpated the *right kidney* from a woman with a urethral fistula and an injury of the right ureter. Prof. Wagner, of Königsberg, states that he examined the *cured* patient, and adds that the fistula had closed. For such affections as abscess, hydronephrosis, echinococcus, and renal calculi, Simon advocates extirpation of a kidney.

Anæsthesia.—Mr. Radu, of Guy's Hospital, mentions that in the Eye department not one case of anæsthesia proved fatal in 3,483, although among 3,224 chloroform cases, 45 became blue in the face and stertorous suddenly, with irregular breathing and pulse.

Venereal Disease in Cochin China.—In a report by Dr. Jules Grinelle, from the *Union Medicale*, on the Diseases of Cochin China, we find the following, which shows the great extent of this evil:

"Venereal affections form a large proportion of the diseases of Lower Cochin China, about one-fourth of the hospital or ambulance cases. Gonorrhœa is more obstinate and more likely to be complicated with orchitis, than in Europe. Buboes are very frequent, whether the result of gonorrhœa, or of sores having a tendency to phagedenic ulceration. It is therefore necessary to avoid having much loss of substance, and depressing cicatrices, to escape this. The writer was in the habit of using several times a day frictions of mercurial ointment into the gland; when the skin became thin and discolored, the lancet was introduced, and the interior brushed with a solution of equal parts tincture of iodine and water, and then bandaged neatly; this was repeated daily, and in ten or twelve days the parts healed. The seton used with the buboes gave some good results.

Phagedenic ulceration was even more likely to attack chancres than a bubo, especially sores on the frænum, on the outside of the prepuce, or on the dorsum of the penis, and so severely, that the entire organ or the greater part was compromised, and consecutive complications were frequent, but secondary syphilis rare. The syphilitic development is much more rapid than in Europe.

Why Coffee is a Stimulant.—We are indebted to M. Personne for an explanation why coffee is a stimulant. He says: The changes which heat effects in the elements contained in the green coffee berry have been little studied. We merely know, from the researches of MM. Baitron and Fremy on the one hand, and of M. Payen on the other, that the brown, bitter substance, and the aromatic principle, are produced by the decomposition of that part of the coffee bean which is soluble in water, and that a larger part of the caffeine disappears during the roasting. It is said that this caffeine is carried away with the volatile products generated in the operation. By roasting coffee in an apparatus which allows of the recovery of all the volatile products, he has ascertained that if caffeine be carried away with the volatile products, it can only be in such small quantity as is not appreciable by weight, and cannot explain the considerable loss which takes place during roasting carefully performed. The loss is experimentally found to equal nearly one-half of the caffeine originally existing in the coffee. He has succeeded in demonstrating that the lost caffeine has been transformed into a volatile base—methylamine, or methylammonia (C. H. N.), which was discovered by M. Wurtz.

Kings County Lunatic Asylum.—The asylum, as completed, has a frontage of 683 feet; linear measure, 1,105 feet. It will now accommodate 700 patients. 818 patients were under treatment during the past year. Of this number 286 were admitted, and 261 were discharged. One hundred and six of those discharged recovered. 80 were improved, 22 were unimproved, and 53 were removed by death. At the date of the Report—July 31st, 1869—there were 557 patients in the asylum. The supposed causes of insanity of patients admitted during the year are as follows: intemperance, in 37 cases; ill-health, in 34; puerperal, in 15; epilepsy, in 12; religious excitement, in 11; domestic troubles and business reverses, in 18 cases. Of the 286 admitted, 134 were males, and 152 were females; 198 were foreigners, and 88 were Americans. The medical officers of this institution are as follows: Edward R. Chapin, M.D., Resident Physician; John A. Mead, M.D., and Eli Warner, M.D., Assistant Physicians.

Trichina Spiralis First Named by Owen.—The celebrated zoologist, Owen, was one of the first to describe this worm, and in 1834 named it Trichina Spiralis.

Influence of Climate on Venereal Diseases.—The evolution of syphilis, according to M. Lagneau, would be less rapid in cold than in warm countries, at Christi-

ania than in France, in France than in the tropical regions. Gonorrhœa, very common in the United States, less so in China, would scarcely manifest itself among the natives of Algeria and the Levant, except those in contact with Europeans. Syphilitic maladies should be cured less readily in cold than in warm countries, and easily with the negroes. When two races come in contact in the same country, syphilis falls most severely on that which had previously been least subject to it. Individuals who contract syphilis in any country would find its effects to amend in a warmer climate, and to be aggravated in a colder one. Syphilis, though universally diffused, would seem unable to establish itself permanently in Iceland, situated almost under the polar circle. According to Livingstone, it would be spontaneously cured in the interior of Southern Africa.—*Jour. de Med. et de Chir. Prat.*

French Academy Prizes.—The Paris correspondent of the *Lancet* says: I append a list of the prize subjects which have been announced for the forthcoming years by the Academy of Sciences. For 1870: the Grand Prize in Physical Sciences—"History of the Genetic Phenomena which precede the development of the embryo in dioic animals in which reproduction takes place without coupling;" the Bordin Prize (3000 francs)—"The Comparative Anatomy of the Annelids." For 1871: Grand Prize in Physical Sciences (gold medal worth 3000 francs)—"Investigation of the Fecundation of Fungi;" Bordin Prize (3000 francs)—"Exhibit the differences and resemblances which exist among the organic productions of every species of the eastern parts of the continents of Africa, South America, and Australia, as well as the intermediary lands, and show the causes to which the differences may be assigned." For 1872: the Prix Serres (£300) will be given for the first time, the subject being "General Embryology, applied as far as possible to Physiology and Medicine."

As a general rule applying to all the *concours*, the Academy announces to competitors for the various prizes that the original essay will not be returned, and that all the works or manuscripts intended for competition must be sent in to the Academy on the 1st of June for each year at the latest.

Chloroform Narcosis.—Dr. Bilbroth, Prof. of Surgery at the Vienna University, has witnessed 12,500 cases of chloroform narcosis, and only 1 death.

Amputation under Chloral.—The *Gazette des Hôpitaux* gives the report of a case in which chloral was exhibited to the extent of producing perfect anæsthesia, under which amputation of the leg was performed by M. Noir. After the operation it was long before the patient recovered his sensibility, and the symptoms for seven hours were most alarming: coma, succeeded by delirium, vomiting, and prostration. It is hardly likely, therefore, that the new agent will be preferred to chloroform, from which the recovery is generally so rapid.

Ovariotomy in Paris.—M. Pean recently related to the Academy of Medicine at Paris that out of ten cases of ovariotomy performed by him, seven had lived. This is a great advance in French surgery.

Croup and Diphtheria.—Dr. George Johnson has come to the conclusion that two distinct diseases have been confounded under the name of croup by many English writers. 1. Acute catarrhal laryngitis or inflammatory croup. 2. Diphtheritic croup, which is always attended in children by more or less abundant and tenacious false membrane in the air-passages, which membrane is absent in inflammatory croup. The latter alone is contagious.—*Med. Press and Circular.*

New Treatment of Rickets.—Mr. Marsh, of Dublin, has employed forcible straightening of the bones in a case of rickets. The patient was put under chloroform, and the tibiæ, which were curved forwards, were forcibly straightened. The practice seems novel and promising.

Amputation at the Knee-Joint.—At a recent meeting of the Royal Medical and Chirurgical Society of London, Mr. Pollock, of Guy's Hospital, related eight cases of amputation at the knee-joint. He thought that on the whole this operation was less dangerous than amputation through the lower third of the thigh.

Hysterical Aphonia.—Dr. Tanner says that he never fails to cure this obstinate nervous disease by means of electro-magnetism. He places the patient in a chair, puts one handle of the instrument moistened into her hand, and with the other touches the tongue. The patient then screams out violently, and thus convinces herself and friends that she has *not* lost her voice.

Copaiba as a Diuretic.—The physicians to the Middlesex Hospital, London, are much in favor of copaiba as a diuretic. It is given in a mixture containing ten minims of copaiba, seven minims of liquor potassæ in a half-ounce of mucilage and caraway water. It seemed to succeed in Bright's disease when other diuretics have failed.

Post-Mortem Temperatures.—About the year 1760, when the study of thermometric readings became a practice in the medical world, De Haen, of Vienna, made the discovery of the singular and interesting fact that sometimes the temperature of the body may rise after death. The discovery, though clearly and definitely announced, was lost for nearly a century, when it was revived by Roger, and carefully followed up by Wunderlich. Quite recently, Adolph Valentin has put together all the most reliable information bearing upon the phenomena in question, and has shown that the occurrence of post-mortem heat is common to all dead bodies, the difference being only in degree. The phenomenon is observed in all cases where the development of the post-mortem temperature exceeds the simultaneous loss of heat by radiation or conduction from the body. Respecting its cause there have been many speculations, some attributing it to the solidification (rigidity) of the muscles, others to chemical changes of decomposition, and others, again, to continuance of so-called vital action after the motion of the heart has ceased.

Inflammatory and Pyretic Diseases. — Professor Bouillaud thus sums up his views on the differences between inflammatory and pyretic diseases:—

1. The excess of fibrin in the blood, in the purely inflammatory condition or process, which for a long time was named "inflammatory fever," proceeds from an *abnormal secretion* or *neoplasm* of the internal membrane of the blood apparatus. This neoplasm is similar to the one produced on the surface of an inflamed serous membrane, to the degree or according to the manner designated by Hunter an *adhesive inflammation.*

2. It is a portion of this neoplasm, or of this pseudo-membranous secretion, which deposits on the surface of the coagulum of blood obtained in the cases above stated—neo-membrane, to which the name of inflam-

matory clot has been given, and the chief constituent principle of which is fibrin.

3. Phlegmasia of the internal membrane of the circulatory apparatus, more or less generalized, and belonging to the so-called *adhesive* form, is one of the fundamental conditions of that production of fibrin in excess, and of the pseudo-membrane of the blood in so-called *inflammatory* fever.—*Lancet.*

TREATMENT OF HÆMORRHOIDS.—M. Richet has published, in *L'Union Médicale*, a clinical lecture "On Hæmorrhoids," in which he advises the use of forceps, brought to white heat, to cauterize piles in several sections. The Professor gives a history of the various modes of operating which have been proposed, but omits to mention Houston's nitric acid plan, and the manner of seizing hæmorrhoidal tumors with a clamp, cutting them off, and arresting hæmorrhage either with nitric acid or the actual cautery—an operation successfully practised by many British surgeons.

A FIRM CEMENT.—Glycerine and Litharge mixed into a paste, furnish an extremely firm cement for iron and stone, as well as fastening stone to iron. The material hardens very quickly, and must therefore be used at once. It is insoluble in water, and only attacked by concentrated acids. Articles joined with it can be used in a very few hours afterwards. Sandstone blocks, joined by this cement, have broken in a fresh fracture, rather than at the point of the union of the original surfaces.

DETECTION OF BLOOD STAINS.—Neumann has recently subjected the question of detection of blood stains to a rigid and exhaustive examination, and has published his results in a book. He recommends to moisten the blood stains with distilled water, and to heat to about 60 degrees Fah. on the glass side of the microscope. In this way microscopic pictures of human and animal blood are obtained of such dissimilarity that the former can readily be distinguished from that of any other animal.—*The Dental Register.*

PUNCTURE OF THE KNEE-JOINT IN THE TREATMENT OF SYNOVITIS.—Prof. Fayrer (*Indian Med. Gazette*), after treating five cases of synovitis, speaks with confidence of simple paracentesis of the joint in the treatment of inflammation, and as he believes it is capable of affording great and rapid relief from pain, as well as of expediting recovery, he has no hesitation in recommending it; but it must be borne in mind that the operation is to be performed with the greatest care, and that every precaution be taken to exclude the air.

THE MINERAL WATERS OF SARATOGA.—Dr. Frederic D. Lente, of Cold Spring, N. Y. (*N. Y. Med. Journal*), wishing to contradict the reports concerning the failure of the original "Congress Spring" of Saratoga, and the diminution of its gaseous constituent, etc., states that these stories are utterly devoid of foundation. The mineral waters taken from the "High Rock Congress Spring," and the "*New* Congress Spring," are often palmed off to the medical profession and the public in place of "*Old* Congress Spring" water; consequently, purchasers should be on their guard.

He remarks that an inordinate dose of Congress water, or a moderate dose at an inappropriate hour of the day, sometimes produces no cathartic effect at all, but, on the contrary, constipates, and induces *malaise;* whereas, a dose of a pint before breakfast, and aided by a slight amount of exercise, will produce, on the same patient, a pleasant and sufficiently cathartic effect.

DEATHS FROM CHLOROFORM.—Twenty-five cases of death from chloroform, gathered from foreign and home medical journals, have been recorded in the *Medical News and Library* during the past year.

THE PLAGUE VISITATION IN LONDON.—When London was visited by plague in 1665, 3,000 persons are said to have perished in one night, and by 1679, the mortality amounted to 100,000 from that source alone. Instead of twenty years, as formerly, the average duration of life now in London is thirty-seven years.

INFANT MORTALITY.—According to Dr. Mapother, in suckling, the average mortality is 37.1 per cent., while among the hand-fed it is 63.9 per cent.

OBSTETRICAL STATISTICS.—Dr. A. S. Todd, of Wheeling, Va. (Statistics of Wheeling), during a period of forty years' practice, has had 1,584 midwifery cases. Of these, 780 were males, and 794 females. Vertex presentations, 1,474; face, 3; arm and shoulder, 9; breech, 2; knee, 1. There were: 4 cases of placenta prævia; retained placenta, 16; hour-glass contractions, 5; twins, 16; double placenta, 11; single placenta, 5; still-born, 32; premature births, 85; anencephalous monsters, 5; club-foot, 2; mother's mark, 3.

TO PRESERVE LEECHES.—A jar filled with caragheen, over which fresh water is poured every day, is a valuable vehicle for the preservation of leeches.

TUBERCULOSIS.—At the Pathological Society of London, on February 1st, Dr. Weber brought forward some clinical facts to show that miliary tuberculosis frequently follows after the deposition of carious matter at a prior epoch. This view is certainly very interesting, and points to the necessity of endeavoring to cure diseased glands in scrofulous patients quickly. Dr. Sanderson exhibited several preparations from Dr. Chaveau of Lyons, showing tuberculous deposits in the mucous membranes of the intestines and bronchi in bovine animals, who had been fed on tuberculous matter. These, according to Dr. Sanderson, originate in the normal adenoid structure of the parts affected.—*Med. Press and Circular.*

SANITARY REFORM IN TURKEY.—A measure of great importance to every town in the Turkish empire has just been decreed. A Hygienic Council, attached to the Ministry of the Interior, has been created, with the function of improving the drainage, enforcing proper street scavengeing, and generally applying measures for the advancement of public cleanliness, both in the capital and throughout the provinces. Its further duty will be to improve existing civilian hospitals, and establish new ones where needed.

SWALLOWING OF A PIN.—Mr. Newstead relates the case of a child, aged eleven months, swallowing a pin. The pin passed through the intestines in three days. It was an inch and a half long, and the point was very sharp.

ANOINTING WITH OIL.—Dr. Knaggs, of Kentish Town, speaks highly of the value of smearing the whole surface of the body of children with olive oil every six or four hours, in cases of atrophy, bronchitis, convulsions, and diarrhœa. So that, after all, we are to have another trial of the old fashion of anointing the body of the sick.

OVARIOTOMY IN A GIRL OF TWELVE.—A professor at Nantes, M. Jonon, has successfully performed this operation. The diagnosis at first, as may be supposed, was difficult. The cyst was multilocular, and adhered in many places; but the patient made a good recovery.

OVARIOTOMY IN SWEDEN.—Ovariotomy has penetrated into Stockholm. Dr. Sköldberg has had 17 successful cases out of 20.

Iodide of Potassium in Periostitis.—Mr. Paget, in a clinical lecture at St. Bartholomew's, advises, in treating periostitis, repeated blisters. Iodide of potassium is useful, 1, in syphilitic periostitis; 2, less so in gouty periostitis; 3, less in scrofulous; 4, it has no power in chronic rheumatic arthritis.

Amputation of Penis.—Messrs. Francis and Grant, of Market Harborough, relate a case of an Irish laborer who snipped off his penis and one testis, when in a fit of delirium tremens, with a blunt rusty pair of scissors. —*Med. Press and Circular.*

A Gigantic Kidney.—Mr. Pearse, of Birmingham, reports that, in a *post-mortem* of a boy four years old, a kidney was found weighing 11 lbs. 4 oz. There was no normal renal tissue in it.

Ligation of the Femoral Artery in a Case of Elephantiasis Arabum.—Louis Bauer, M.D., M.R.C.S., of St. Louis, reports, in the *St. Louis Med. and Surg. Journal*, an aggravated case of elephantiasis arabum of six years' standing relieved by ligation of the femoral artery immediately below the profunda. More than 18 years have elapsed since the introduction of the ligature in elephantiasis arabum by Dr. Carnochan, and but 23 operations have been performed with a view to its relief. So far as statistics serve, more than 25 per cent. of the patients have derived permanent relief from the ligatures.

The Soft French Bougie.—Sir Henry Thompson gives most emphatic preference to the elastic instruments in the treatment of stricture, especially the very soft and pliant olive-tipped French bougies and catheters.

Acarus Sacchari.—Dr. Hassal, of London, found the *acarus sacchari*, which is akin to the *itch* insect, in sixty-nine out of seventy-two samples of raw sugar. Not a single specimen could be found in refined sugar.

Carbolic Acid Soap.—A pharmaceutist sends the following formula to the *Drug. Circ. and Chem. Gazette* for preparing the *Sapo Desinficiens phenylatus Hageri:* Take freshly prepared cocoa-nut oil soap, 150 parts, and fuse; then add a solution of—

Alcohol, 10 parts; carbolic acid, 6 parts; caustic potassa, 2 parts; oil of lemon, 1 part, and mix with stirring. To be poured into moulds.

How to Study the Hepatic Glands.—Dr. H. D. Schmidt, of New Orleans, La. (*The New Orleans Journal of Medicine*), affirms that it is indispensable, while studying the various forms of the "hepatic glands" and their ducts, that the specimens should be well injected with Prussian blue. In such preparations the epithelial cells can still be observed. Uninjected specimens should be resorted to for the examination of the structure. The locality which he usually prefers for the latter purpose is on the inferior surface of the liver, and between the larger branches of the hepatic duct. The glands are readily recognized by their yellowish pink color, by putting a fresh liver under water and carefully removing the peritoneum from that part. They are then dissected out under a magnifying glass of low power and placed on a glass slide. Being well covered with water, they are thoroughly freed from the surrounding fibrous tissue by means of fine curved needles; this is best accomplished on the dissecting stage under a magnifying power from 8 to 10 diameters, and by transmitted light.

While dissecting out these glands, it often happens that a small hepatic duct is cut, and small portions of its epithelium escape in the form of small round yellowish bodies. These must not be mistaken for the glands. The error may be detected by the difference existing between the epithelial cells, those of the hepatic duct being columnar.

The Discoverer of Vaccination.—The churchyard of the village of Worth, Dorsetshire, England, contains a memorial tablet with the following interesting inscription: "Benjamin Jesty, of Downshay; died April 16, 1816, aged 79. He was born at Yetminster, in this county, and was an upright, honest man, particularly noted for having been the first person known that introduced the cow-pox by inoculation, and who, for his great strength of mind, made the experiment from the cow on the wife and two sons in the year 1774."—*Med. and Surg. Reporter.*

Physical and Moral Transmissions from Parents to Children.—E. P. Le Prohon, M.D., of Portland, Me. (*The Jour. of Psychological Medicine*), publishes an extended paper on this subject, and concludes as follows: The best means to oppose hereditary transmissions consists in the interdiction of marriage between parties who inherit incurable maladies, and who will infallibly transmit them to their progeny. Families who desire to have their children married take the greatest care to conceal the incurable evils which they inherit, and they unite in marriage a scrofulous, leucorrhœic, nervopathic, hysterical daughter, to a young man who believes her to be perfectly sound. Would any young woman consent to marry a young man who is epileptic, impotent, or syphilitic, if she had a previous knowledge of his secret disease? In the same category are persons affected with deafness, partial blindness, hallucinations, latent insanity, furious passions, etc. To unite in marriage such individuals, and make a secret of their constitutional taint, is a monstrous piece of imposition, which requires a release from the civil contract of marriage. Marriages between parties where consanguinity exists should also be interdicted, because such unions produce bad fruit, besides increasing all the infirmities which already exist in families coming from the same source.

The only security in combating and preventing the germ of disease, is in matrimonial associations. A robust constitution united to one of a feeble temperament will make up, in a measure, the deficiencies of the latter, and the fruit derived from such a union will be found satisfactory in the first generation; and, if the matrimonial association is continued according to this rule, at the end of the second generation progeny will then be sound. Thus the union of a lymphatic temperament with a dry, bilious temperament seems to be the best accouplement to modify or destroy the scrofulous taint in one of the parties.

New Publications.

Books Received.

The Indigestions, etc. By Thomas King Chambers. 3d edition. H. C. Lea. Philadelphia. 1870.

The Preventive Obstacle, or Conjugal Onanism, etc. By L. F. E. Bergeret. Translated from the third French edition by P. De Marmon, M.D. Turner & Mignard. N. Y. 1870.

A Practical Treatise on the Diagnosis, Pathology, and Treatment of Diseases of the Heart. By Austin Flint, M.D., Professor of Practical Medicine, Bellevue Hospital. Second edition. Philadelphia: H. C. Lea. 1870.

Original Lectures.

ANTIPHLOGISTIC TREATMENT IN DISEASES OF CHILDREN.

REMARKS MADE BEFORE THE N. Y. MEDICAL JOURNAL ASSOCIATION, APRIL 15 AND 22, 1870.

By A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Lecture I.

Mr. President:—I approach the subject announced for this evening with some hesitation, for I am aware that each of my hearers who has had any extended experience in practice, and has employed the facilities, here so abundantly afforded, for keeping up with the progress of medical knowledge, may be just as competent as myself to speak upon it, and may perhaps already anticipate nearly all that I shall have to say. Yet, at least to furnish a basis for profitable discussion, I shall first offer some preliminary remarks upon the pathology of inflammation and fever, and the causes of their frequent occurrence in early life, and then take up, one by one, several of the remedial agents known as antiphlogistic, principally the following: depletion, cold and warmth, salts; acids, vegetable and inorganic; digitalis, veratrum viride, aconite, quinine, ergot, opium, camphor, alcohol, iodine, mercury, and electricity.

INFLAMMATION AND FEVER.

The definition of inflammation has frequently been changed. It has been greatly dependent on the results of microscopical investigations, particularly those on the development, nature, and transformation of the cell. Schleiden and Schwann's discovery of the existence of the cell was at once made available for the theory of inflammation by Rokitansky. Goodsir and Redfern followed up both his investigations and his theory by their investigations on cartilage, and Virchow by his studies of embryology and the connective tissue. Since, Schultze, Brücke, Recklinghausen, by their labors on the physiological nature and also the pathology of the cell, Cohnheim and others by the discovery of its extensively migratory character, have changed the doctrine of inflammation to a certain extent. At all events we must admit one fact, viz., that for some time past the clinical theory of inflammation has been superseded by that gained from the anatomical points of view. Instead of symptoms, we studied and counted the finer structure. The increased life of the cell was the essentiality of inflammation. Then again, in opposition thereto, the inflamed part and its existing cell structure were considered of no account, but the emigration of colorless blood corpuscles rivalled all the former assertions and theories as an independent and all-powerful competitor. Of the old theories of inflammation nothing remained intact.

As long ago as 1846 (Philosoph. Mag., vol. 29, pp. 271, 398), Waller, when experimenting on the extended living tongue of the frog, came to the conclusion that pus corpuscles were identical with colorless blood-corpuscles, and that pus was not formed in and from blastema, as was always believed before, but that an actual perforation of the walls of blood-vessels was a frequent process. He says, "In consequence of the striking resemblance (between white blood corpuscles and pus corpuscles) observers have already supposed that the corpuscles of the blood give rise to those found in mucus and pus, and that these are simply corpuscles extravasated or filtered from the blood. An important observation has, moreover, corroborated this theory, namely, that of the accumulation of the corpuscles at the inner sides of vessels which are subjected to any prolonged irritation. On the other hand it has appeared to other physiologists so improbable to suppose the perforation of the capillary vessels by the corpuscles, that they have come to the conclusion that they are not derived from the blood, but, like semen or milk, are formed in the secreting surface, in virtue of some plastic power of the fluids which are effused upon it." From this quotation it is evident that Waller had given up and did no longer participate in the blastema theory, but in spite of his direct observations he and his theory were forgotten. The blastema theory was refuted, or at least thoroughly shaken, first by Goodsir and Redfern, then by Virchow. I have alluded to their investigations, made without regard to Waller, until Cohnheim, 1867, and Stricker and many followers revived the views of this observer.

Bowman, like Redfern, lays particular stress on the disorders of nutrition in the explanation of the inflammatory process. Thus, the discoloration of the cornea in inflammation is the result of increase in number of the cornea corpuscles. His facts and theory were not shaken, and had the field undivided, until Recklinghausen discovered the pus cell to be both contractile and migratory. Cohnheim succeeded in 1867 in fixing in an intact condition the corpuscles of the cornea by means of chloride of gold, and thereby found that they have nothing whatever to do with the formation of pus. In inflamed tissue nobody ever proved the divisibility of cells, but the permeability of uninjured blood-vessels became established.

The principal qualities of inflammation are, 1st, exudative, 2d, nutritive changes. The first was emphasized by Bennet and Rokitansky. With them, inflammation was completed with exudation, effusion, or extravasation. But it became known that tissue not endowed with blood-vessels showed the characteristic disorders of inflammation. The second got the ascendency by the observations of Goodsir, Redfern, and Virchow. Exudation was not positively dismissed, but the inflammatory process of blood-vessels was not considered as absolutely necessary. Virchow first insisted that connective tissue with its persistent cells was the only seat of inflammatory changes, and whatever was not connective tissue could but perish in that process. Remak and Buhl claimed, first, the same privileges for the epithelium cells, especially since Remak and Reichert had found the identity between epithelium and gland. Holm went still further, showing that liver cells would not only increase in number, but also get transformed into fibre. Virchow again, in contradiction to his own former theory, found that the muscular nuclei not belonging to connective tissue increased in the inflammatory process, and that the connective-tissue cells increase principally by augmentation of the nuclei inside. *His* concluded that new capillaries were formed from cornea cells; Leidesdorf and Stricker proved that capillaries may increase in number; and Eberle, Aeby, and Auerbach demonstrated that the walls of the very capillaries consist of nothing but epithelium, thus preparing for Cohnheim's discovery (preceded by Waller), according to which the white blood corpuscles pervade and perforate these walls of capillaries, which are composed of epithelium, by the thousand; and for his further theory that every deposit of pus is but emigrated white blood. There is, then, nothing exempt, it appears, from the liability of participating in the inflammatory process, except perhaps the nerve cells, which are not yet proved to participate in inflammatory new formation, although they are a very frequent seat of degeneration of the granular or fatty variety.

This theory of the formation of pus is very probably but one-sided. The formed elements of which pus consists, besides the fluid, which is identical with blood serum, are like white blood corpuscles, and are proven to come directly from the blood-vessels But there are other modes of formation of pus. Division of pus corpuscles, especially in profuse suppuration, is more than probable, for such a subdivision has been demonstrated in the epithelia, which are apt to increase, 1st, by direct division, 2d, by endogenous new formation, and in the connective-tissue corpuscles which, under those circumstances, also assume the character of pus.

After all, Virchow was right in stating the necessity, or rather the occurrence, of nutritive disorder in inflammation. But he was not complete, for surely there are emigrations of white blood corpuscles, without nutritive changes. Further, there are new formations which are not inflammatory, but still nutritive changes. Nor is the combination of *nutritive change* with *emigration of white blood corpuscles* sufficient for the definition of inflammation, but *exudation* is also required. Its importance is recognized by Virchow, but only so far as the presence, not so far as the process, of exudation is concerned. "It is not the action of the heart that drives it out, but the action of the elements of tissue that draws it out"

He found that hyperæmia is not always followed by inflammation, and thereupon he built his theory, and his defence of the necessity of a traumatic cause. But wherever there is inflammation there is always a disorder of circulation. Might not a traumatic influence change the motion of the fluid in the cells, as they are independently excitable? Certainly. But this excitation cannot be carried from cell to cell, especially not in connective-tissue cells, which are isolated from each other. The current of blood serum is important for the life and development of cells, as it acts in two ways,—first as a mechanical stimulant, and further as material of nutrition.

Thus in inflammation we require a number of conditions or constituents:—

1. Traumatic influence on blood-vessels—that is, especially, capillaries—by either changed action of the vaso-motor nerves or direct injuries to the walls.

2. Disorder of circulation. "Calor" and "rubor" of the old schools are not required, for cold-blooded animals exhibit neither.

3. Exudation of the fluid and formed elements of the blood.

4. Nutritive disorder, in growth of, and changes in, the cells. Persistent cells may be transformed into living changeable ones, which may undergo multiplication by subdivision and endogenous generation. This changeability, or "lability," is different in different organs; it is very slight, if at all existing, in horn and fully-developed connective tissue. It requires to be seen in future whether this latter can still be melted down, in spite of its complete organization. It is very probable, as I hope to show in the future. If it is, there is hope for trachoma, cirrhosis of lung and liver, tetanus, etc. The age of a tissue may also affect its stability. Some elements of the cornea may not be transformable after a certain time. Says Hirsch,* whom I gratefully quote for his lucid description of the theories of inflammation and fever, and to whom, therefore, I am under great obligation: "There are matrons who will bear no children, under no matter what influence or coercion."

5. New formation of homogeneous tissue. We shall see in future that this last one of the necessary constituents of inflammation is the peculiar characteristic of what is called chronic inflammation.

At this juncture I lay stress again, for its clinical importance, on the variety of constituents and the variety of causes of inflammation, simply pointing to the various modes in which an inflammation may show itself. It is but natural that it will differ according to individuality, age, condition, locality, or tissue. And these differences enforce the practice of individualizing in every given case. Thus the rules for the treatment of a certain inflammation, as known in our dictionaries and indices, must always be of a general character only. We have to deal, not with a Greek or Latin name, nor with a parasite that is to be expelled, but with the living tissue of a single individual, with its special dispositions, resources, idiosyncrasies, etc.

As the first amongst the constituents of inflammation we mentioned change in the walls of the blood-vessels. This may, as above said, be the result of direct injuries, or of changed function of the vaso-motor nerves. It is practical to speak in this connection of one of those symptoms of inflammation which are the most common subjects of clinical observation, and that one which, by itself, has a great influence on both the course of the disease and the indication for treatment. I mean fever.

We recognize fever by increased temperature. We are interested in observing the temperature of the local inflammation, and of the blood in general. We notice increased temperature in an inflamed part, but it never exceeds that of the blood, as measurements instituted in the vagina and rectum will invariably show in all cases in which the fever is due to a local cause. Besides, there are many fevers which have no local source, but a general cause. Therefore, the increase of metamorphosis of substance, which is the source of the increase of temperature, is not local at all.

What is its source, or cause, or seat?

I shall not dwell upon the physiology of the nervous system, as I do not mean to carry owls to Athens. I allude only to the fact that certain nerves have the function of being moderators, controllers, of the actions of certain organs. Thus the pneumogastric nerve moderates undue haste in the action of the heart. Irritation of that nerve renders the heart's action slow; paralysis, for instance, in consequence of section of the nerve, or of the proper lesion of the medulla oblongata, renders it uncontrollably rapid. Thus the splanchnic nerve is the moderator of the intestinal motion. Thus Setschenoff has found a moderating centre in the brain of frogs for their spinal reflex action; when this centre was destroyed, the reflex action was uncontrollable. It appears we shall have to fall back, to explain many symptoms of fever in general, on a moderating centre for metamorphosis of substance and the regulation of temperature, situated in the brain, which, when not altered, keeps them at their steady pace, when paralyzed, loses its reins. Thereby the muscles of the blood-vessels, thereby also the unstriped muscle of skin and glands, would be unchained; and dilatation of blood-vessels, profuse secretion from the intestine, colliquative diaphoresis, would ensue. This affection of the moderating centre need not be a primary affection; a secondary congestion, or irritation by a tumor, would suffice to give rise to all the symptoms. The fact of the enormous increase of temperature in so-called tubercular meningitis, when paralysis and death are imminent, shows to what extent the above theory is justified.

* *Dr. Theodor Hirsch*, The Development of the Doctrine and Treatment of Fever since the Commencement of this Century. Berlin, 1870, pp. 106. I would also direct to another author, to whose labors I am indebted in collecting much of the material laid before you this evening: *S. Stricker*, Researches in the Institute for Experimental Pathology in Vienna, in the Year 1869. I. Vienna, 1870. Pp. 110, and 4 plates.

Still, the local affection of this moderating centre, whether primary or secondary, is not the only source of fever. At least, we do know of general processes, in the blood or tissues, which give rise to very high fever without primarily affecting that centre. Thus we know that the presence of putrid material, or ferment, in the blood raises the temperature. Even substances formed in the very organism, when reabsorbed into the blood, will have the same effect. The detritus of a caseous gland produces violent fever, and is the cause of new formations in lungs and brain. Even large quantities of water or serum will act in the same manner when introduced into the system; or an abnormally large quantity of meat introduced into the stomach or blood will bring on increased temperature, lassitude, and muscular pain, by temporarily accumulating lactic acid and phosphate of potassa. Even the rapid absorption of normal elements of tissue after a venesection will produce, after the first fall, a rise in the temperature.

Thus it is not improbable that fever will result not only from an affection of the moderator in the brain, but also from independent changes in the blood. It cannot be denied, however, that the effect of distant causes of fever on the cerebral centre may be so rapid that the proximate cause of fever has always to be looked for in the brain.

No matter what the cause of the fever may be, the high temperature and increased waste of tissue are by no means indifferent. Those diseases in which there is but little waste or sufficient reproduction take a favorable course, for instance typhoid fever in infancy and childhood. In others, where the waste is greater, the danger increases. 0.667 per cent. is a fair average of the loss by fever per diem (1 per cent. in the crisis). As a loss of 40 per cent. of the weight of the body destroys life, according to Chossat, a fever of eight weeks would kill a patient. Complete inanition takes 1.5 per cent. of an animal's weight per diem; thus twenty-six days of inanition will destroy life, and inanition and fever combined will terminate a case in about twenty days. This, however, is not the only cause of suffering or death. High temperature alone will produce degeneration of tissue, with paralysis of brain or heart. But lately, Zenker has demonstrated changes in the voluntary muscles similar to fatty degeneration, which occur in typhoid fever, and depend exclusively on the high temperature of the blood. But the degree of temperature alone is not a good measure of the power of a disease or of the imminence of danger. It will depend on individual tendencies. It rises more easily and rapidly in the young. It may be apparently low, also, in proportion to the danger of disease; for evaporation may reduce the temperature as fast as it is generated. General perspiration in rheumatism, or when plenty of water is drunk, keeps the thermometer low; and it is the general experience of practitioners that the fossa axillaris must be well dried before the thermometer is applied.

The treatment of fevers has always been in accord with the scientific opinions of the times, or rather of the pathologists who made and upheld the opinions of their times. Thus *P. Frank*, in his "modus curandi, etc.," insists on removal of the causes. He considers the fever in the light of a wholesome reaction of the system. Where the powers of the system are simply suppressed, not lowered,—"vires suppressæ,"—he forbids roborants and stimulants. *Reil*, another great pathologist of the first part of this century, admitted that he had too little scientific knowledge of the nature of fever. As anti-febriles proper, he looked upon remedies that "blunted the increased irritability and thereby stopped the fever;" and empirically treated inflammatory fevers with antiphlogistics, typhus and typhoid with sedatives, paralytic conditions with stimulants. Amongst his antiphlogistics are cinchona, warm and cold baths (after the teaching of Currie, in 1797), and, already, camphor and opium. *Brown* relied on stimulants, Broussais and Bouillaud on powerful so-called antiphlogistics and venesection to exhaustion. *Schönlein* allowed himself to be guided by the prominent features of the case. In slight fevers he followed the expectant method; in acute inflammations used antiphlogistics; in increased irritability narcotics, in torpor roborants and excitants. *Traube*, another great Berlin pathologist of to-day, and the first who measured temperatures on a large scale, advises in inflammatory fevers, at the right time, small depletions, calomel, and digitalis: the proper time being a little previously to the expected crisis.

As early as 1854 *Virchow* published his views on the treatment of fevers. His indications are two,—the first to reduce the temperature, the second to moderate its source. The first is indirect and symptomatic; the second directly anti-febrile. The first indication is fulfilled by the proper diet, cold, depletion, salines, and acids; the second by digitalis, quinia, and arsenic. These latter are nervina, and act as excitants of different spheres of the nervous system. Stimulants may become indicated by symptoms of paralysis, tonics and roborants by imminent inanition. But less emphasis is laid on derivation to skin, bowels, and kidneys, with a view to bring on or aid a crisis. These principles of Virchow's are still valid at our times; being expressed in general terms and requiring application to and modification by individual forms of diseases, or cases. This much is sure, that they have given rise to a large number of fruitful researches concerning the effects of single remedial agents. Many of the direct means of treatment, however, we need not count among these, and they will not claim our immediate attention this evening. Thus, for instance, the incision of an abscess giving rise to fever, the washing out of the poisonous secretions of endometritis, the removal of a foreign body producing local and general irritation, will not be mentioned to-night, although each of them may be the prominent anti-febrile in an individual case.

THEIR FREQUENCY IN EARLY LIFE.

The fact of the great frequency of diseases in early age, and especially of inflammatory diseases, is too well known to require any further allusion. Both liability to disease and mortality grow less with every hour or day of the newly born and of the infant. And it is a remarkable fact that a number of organs are very rarely affected, and others very commonly the seat of lesion and abnormal function. This difference depends on the physiological function of the several organs. Diseases, that is, pathological processes, are principally found in such organs as are most active physiologically; while those which are at rest, or relatively so, are less liable to be changed in their anatomical condition and functional duties. This is so true, that amongst all the fœtal organs it is principally the heart which is apt to become diseased, it being the very organ which is more active than the rest; and of the several parts of the fœtal heart it is just the right side (it being more exempt from primary disease in the adult) which is oftentimes the locality of a change.

In the born infant such organs as perform no functions, or but limited ones, are seldom affected. The thymus gland exhibits more changes during uterine life than after birth, and particularly after the first year, at

which period it commences in earnest its downward march of atrophy. The sexual organs, too, show but few anomalies, simply because they are not called upon to perform any functional work, and because even their physiological development makes no unusual strides.

But almost all the other organs are liable to suffer from the first minute of life, in consequence of the altered conditions of existence and of functional work. Circulation is entirely changed; the lungs become, together with the heart, the centre of it. Thus it is that at no period of life do we see more pulmonary diseases than in infancy; thus it must be explained, also, which is a remarkable fact, that genuine lobar pneumonia, with rapid and extensive exudation, is a frequent occurrence in the very first months of extra-uterine life; while the usual form of pneumonia in infancy and childhood is the catarrhal variety. Further, the rapidity with which changes take place in important organs must also be explained by the very same fact of the sudden changes and new impulses in the distribution, and, I may say, assaults of the blood. Many cases of sudden death, sometimes unexplained, are the results of this physiological occurrence, which is augmented and exaggerated into pathological functions. I remind you only of the frequent occurrence of encephalitis in the very young, with fatty degeneration of the nerve cells, sometimes very extensive, sometimes but in small and circumscribed localities, but always sufficient, by both the direct destruction of the nervous centre and the collateral œdema, to subvert life more or less suddenly. It does not matter whether it is complicated or not with ulceration of the cornea, as described by Virchow and others, or with spasms or paralysis. I should further allude to the frequency of trismus and tetanus of the newly-born as in part depending on the sudden changes of circulation, which are so very apt to result in the peculiar hyperplastic degeneration of the spine in that affection. That such is the case is readily, besides other causes, proved by the excessive mortality from trismus in the infants of some parts of Northern Europe, where the newly born, in cold climates, in any sort of weather, are carried to the cold, dreary churches to get baptized. The frequency of conjunctivitis in the new-born may also be, in many cases, the partial consequence of the new impetus circulation has received after birth, and the insufficient resistance which the loose tissue of the conjunctiva offers to the dilatation of blood-vessels and consecutive effusion or exudation. Even hemorrhages occur more frequently in the young than in the old—the oftener, the nearer the first hour of life. Hemorrhages in the sclerotica, brain, and spine are not at all uncommon without the slightest appreciable presence of a proximate cause (as for instance hooping-cough, where extravasations are so frequently found). Paralyses depending on spinal extravasations, occurring during, or rather right after birth, are by no means rare or exceptional, not to speak of the numerous cases of so-called infantile paralysis. This form of paralysis—called, for want of a diagnosis, by some infantile, by others essential or dental—is certainly in most cases the result of spinal extravasation. Both its sudden appearance and its very rapid recovery up to a certain degree, and finally its absolute obstinacy, speak for this assertion. Let me further speak of the usual discoloration of the skin a few days after birth. I do not speak of the cases of genuine jaundice, depending on the changed relation between the biliary ducts and the blood-vessels of the liver,—the latter absorbing bile because part of their contents is cut off with the establishment of pulmonary circulation, by which process the liver is dethroned from its position as fœtal centre of circulation,—nor do I refer to the grave form of icterus depending on the pyæmic process. But I allude to the mild cases of so-called jaundice, which are but the change of color depending on the discoloration of the hæmatine deposited into and under the skin. It may be well compared with the change in color of subcutaneous or intra-cutaneous extravasations.

In my book on "Dentition and its Derangements, N. Y. 1862," I have drawn a picture of the rapid physiological changes taking place in the infantile head, and of its liability to consecutive pathological changes. Here I confine my remarks to a single allusion to that fact, because we have to become acquainted with the, I might say, physiological necessity of frequent congestive or inflammatory diseases of that portion of the body. Face, cranium, and brain grow rapidly; the fontanelles and sutures close; the brain grows in size and weight, the bones in thickness and shape, the teeth grow and protrude, the gums increase in thickness. The salivary glands develop in the third and fourth months, giving rise to copious secretion, which in the first commencement has neither the chemical character nor the physiological power of genuine saliva. The muciparous follicles, spread over the whole inside of the buccal cavity, with the exception of the gums, also grow in size and activity. These are the principal normal changes, and what do we see as the frequent exaggeration of this physiological state? Hyperæmia of the skull, even in non-rhachitical children, of the meninges and the brain substance, meningitis and encephalitis; congestive condition of the skin of face and head, erythema, eczema, and impetigo, usually with swelling, frequently with inflammation and suppuration of the numerous lymphatic glands of the neck; tumefaction of the salivary glands, inflammation of the gums, inflammation, erosion, and ulceration of the muciparous follicles of the mouth and all other forms of stomatitis and pharyngitis. Nor are the kidneys exempt. The rapid change in nutrition and elimination crowds a large amount of nitrogeneous substance into and through the kidneys. On and after the second day of life, down to the fourth week and later, we find in the pyramids of the kidneys orange-colored deposits of uric acid; these are so regularly found that their presence is of medico-legal importance; they are a frequent cause of urinary difficulties, and even of the formation of gravel and calculus in the young, the central portion of these stones being formed of uric acid, around which phosphates will accumulate afterwards.

Furthermore, the very circumstance that one or a few fœtal organs will be at rest, or relatively so, after birth, is a cause of physiological and sometimes pathological changes in the neighborhood. The thymus, as I have already stated, becomes stationary after birth, and soon begins to decrease. In proportion to its diminution in size neighboring organs will grow. For instance, the thyroid gland, weighing but a quarter or one-half of a drachm in the first year, weighs 2½ scruples in the second, a drachm in the third, 2½–3 drachms in the ninth year, an ounce or 1½ ounce at the age of twenty or thirty—a little more in the female than in the male. And I have no doubt that the fact that in cases of general malnutrition, and even without it, the bronchial glands are apt to be swelled; that in reality they are the first to be the seat of hyperplastic and particularly caseous degeneration, whenever such degeneration is found anywhere in the system, is partially due to the closing up of a range of circulation in the neighborhood. We have a right to conclude so from what we notice in the abdominal cavity. With the moment of birth the liver ceases to be the centre of circulation. From that moment it is supplied with less blood; from

that moment it diminishes in size; from that moment also begins the development of the intestinal follicles and the mesenteric glands, which are destined to play such an important part in the household of the organism. Thus it is proven that hyperæmia and its physiological and pathological sequelæ will result from the normal development; the frequency of congestive and inflammatory diseases is therefore no matter of astonishment.

As all of the gentlemen who have honored me with their presence are aware of every word I have had to say on my subject, I should not have deemed it necessary or prudent to allude to these facts; but I have thought I owed it to myself to show that I myself did not overlook their importance. Nor do I overlook the other factors which render infancy and childhood liable to inflammatory diseases. The time of weaning has arrived; I will surmise that the mother's or nurse's milk has worked no injury. Then comes the critical period. No sufficient development of salivary apparatus, teeth, or stomach; improper food, perhaps; gastric catarrh, intestinal catarrh, consecutive hyperæmia and enlargement of mesenteric glands. Either hyperplastic condition of their connective tissue and compression and atrophy of their glandular tissue and the ducts, and incurable marasmus; or caseous degeneration, enlargement, softening, absorption of the detritus, caseous lymphatic glands all over the system, caseous pneumonia, perhaps tuberculosis. Such is the list of ailments the connection between which is at present clear to everybody. They are just as many dangers to the infant's or child's existence, and the connection between them is so intimate that a slight deviation of a normal physiological function is sufficient to set the ball a-rolling.

Nor is this all; for with the increase of normal physiological action there will be other dangers. None of the diseases which are known to spread by contagion, by a ferment, are frequently seen in *very* young infants. The ferment is received into the system by the lungs; their function is but incompetent in the very young; sometimes their breathing is very shallow. Everybody knows how difficult it is, and almost impossible, to get a new-born or a very young infant under the influence of chloroform. Thus the ferment will not easily enter such lungs, and through them the blood. Thus it happens that scarlatina, measles, hooping-cough, etc., are not very frequent in the very young. With every month, however, the liability to them increases; and at the period at which the lungs get more developed, when circulation gets more powerful and more uniform, at the time when, with the closure of the fontanelles, in the beginning of the second year, and with commencing locomotion, and with active assimilation of more solid food, a certain power and equilibrium of circulation are obtained, all those diseases will increase in frequency, and as a rule in severity also. It is not at all uncommon that a baby, although taken with scarlatina in a family where the older children are seriously affected, escapes comparatively unharmed.

What I have said briefly, even fragmentarily, although I have tried to say it coherently, goes to show or explain the frequency of feverish, congestive, and inflammatory diseases in infancy and childhood. There is another anatomical fact or two which ought to be taken into account, viz.: the condition of the heart and of the muscular system. The muscles of the infant are feeble; thus the support given to the circulation of the adult by their elasticity and powerful contraction is wanting in infants. But the heart of the infant is much larger and heavier in proportion than that of the adult. The heart of the newly-born has a weight of from ten to thirteen drachms, that of the adult of about eight ounces. Thus the heart of the adult weighs but six times as much as that of the newborn, while the weights of the bodies are in the proportion of at least twenty to one. It is at once evident, although the feebleness of the muscles of the body is greatly counterbalanced by the weight and power of the heart-muscle, that the slightest disproportion between the two, the most minute change in any part of the system, is liable to seriously injure circulation and the economy at large.

Thus inflammatory diseases are very frequent in early age, and, moreover, their symptoms very urgent. The nervous and circulatory irritability is great at that period of life; the skin is thin, and liable to suffer from exposure or sudden changes of temperature; all the several organs, being but recently trained to their functions, and but gradually getting accustomed to fulfil them, exhibit less resistance to disorders or injuries. Constitutional diseases, especially of a fermentative character, are very frequent, and leave often behind them either local diseases or unusual impressibility of the whole system. In any given case, the consequences are more readily visible and injurious than in the adult; the pulse is readily influenced,—that is, the heart's action increased to over-exertion and the dangers of paralysis; temperature is very high, even in slight affections; and although it is true that in such it will sink as readily as rise, the changes which increased temperature will work, and the dangers it will carry with it, as described before, make the exact watching of the temperature in feverish and inflammatory diseases of infants and children a positive necessity. Diagnosis, prognosis, and treatment are equally interested in the measurements of the heat of the body. Thus, while I know I have to beg your pardon for the length and prolixity of these statements and remarks of a preliminary character, I feel to a certain extent justified in speaking not too briefly of those diseases the treatment of which was to form the subject of to-night's conversation.

(To be continued.)

CLINICAL LECTURES ON THE DIAGNOSIS AND TREATMENT OF

STRICTURE OF THE URETHRA.

By J. W. S. GOULEY, M.D.,

PROFESSOR OF CLINICAL SURGERY AND OF GENITO-URINARY DISEASES IN THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

Lecture IV.

STRICTURES AT THE MEATUS URINARIUS, AND IN THE FOSSA NAVICULARIS.—THEIR NATURE, DIAGNOSIS, AND TREATMENT.

Gentlemen:—To-day we shall occupy ourselves with the study of stricture at the external orifice of the urethra, and of that portion included in the space occupied by the glans penis.

These strictures are congenital, traumatic, chancrous, or gonorrhœal in their origin.

In the congenital variety there are sometimes two narrow external orifices; a lower one, through which the urine flows, and an upper, terminating in a cul-de-sac, at a distance varying from half an inch to three or even four inches. Or there may be, just within the meatus, a crescentic valvular fold, a thin diaphragmatic membrane, else a mere narrowing of the outlet, which in that case is usually high upon the glans, just short of constituting epispadias. Or there may be slight

hypospadias, with a very narrow, nearly transverse slit at the base of the glans (Fig. 17).

Congenital phimosis and narrowing of the meatus urinarius are often associated; when there is a very small preputial orifice, circumcision should be done without delay, that the constriction at the meatus may be treated. Case 15 in Lecture III. is a good illustration of the coexistence of phimosis and congenital stricture.

These abnormities belong properly to the category of malformations, but clinically they may be considered as strictures, for they present similar symptoms and sequelæ, and have to be subjected to the same treatment.

The traumatic variety sometimes results from frequent and rude catheterism, wherein the meatus is repeatedly contused. In a case of the kind, observed by one of my colleagues, the external orifice was red, narrowed, indurated, and presented the appearance of malignant disease. The patient was an old man who had been in the habit of introducing a rough instrument several times a day, to relieve himself. As soon as he had learned to pass a properly constructed instrument, all the unpleasant symptoms disappeared. Generally, however, when these patients seek surgical aid, the tissues are found so altered as to demand more active interference. Another form of traumatism is amputation of the penis. This operation, when done in the usual way, is followed by a very narrow and troublesome constriction of the extremity of the urethra. I can remember several such cases treated in Bellevue Hospital, many years ago; one man in particular, who died from this cause after several years of the most intense suffering. The orifice would barely admit a small probe. The poor fellow spent most of his time in vain endeavors to relieve himself, and finally succumbed with cystitis pyelitis and disorganization of the kidneys. Such untoward results can be averted by cutting the cavernous about three quarters of an inch shorter than the spongy body, and making three rectangular flaps of the latter and stitching them to the skin around the stump, so as to make a rudimentary glans penis. Let me give you another very interesting example of traumatic stricture at the external orifice. About five years ago, my friend, Professor Van Buren, invited me to examine one of his patients—an adult—who for a long time had been suffering from dysuria. My attention was called to the extremity of the penis, which was abnormally flat, and to a narrow meatus. The patient had been circumcised in infancy; this had given a clue to the nature of the trouble, and the Doctor felt satisfied that a slice of the glans penis, including the meatus, had been cut at the time of the operation. The usual free division of the external orifice was made, with the most satisfactory result.

Those of chancrous origin invade not only the meatus, but often extend half an inch or even more in the fossa navicularis. Last autumn, a young gentleman consulted me for a chancroid of the meatus, which had extended nearly three-quarters of an inch in the urethra. It healed shortly after, and left a deeply depressed elliptical cicatrix, with an orifice capable of receiving but a No. 2 bougie. In November, 1868, John M., aged 27, came to seek relief from troublesome dysuria, solely dependent, as he thought, upon a phimosis, the consequence of chancre. He had had gonorrhœa ten years previously. None save No. $\frac{1}{2}$ gum bougie could be passed. Circumcision was performed to facilitate the diagnosis. After having slit open the prepuce, I found that about three-fourths of the glans penis had sloughed, and the meatus contracted to No. $\frac{1}{2}$ bougie. It was freely divided above and below, the redundant prepuce was excised and interrupted sutures applied. There were two strictures of gonorrhœal origin, $2\frac{1}{2}$ and $5\frac{1}{2}$ inches back; these were readily dilated to No. 16. Catheterism with No. 16 was continued one year. No recontraction.

On February 16th of this year, I showed you a man who had been suffering from dysuria and constant dribbling, due to a constriction at the meatus,—through which but a small probe could pass,—from a chancrous ulceration that had carried away nearly the whole glans penis. As soon as the stricture was divided these symptoms ceased, and when the wound had healed the passage was sufficiently free to receive No. 13 sound.

Stricture at either end of the fossa navicularis occurs much more frequently as a consequence of gonorrhœa than it does from the three causes before mentioned. It generally coexists with one or more constrictions in the deeper part of the canal. There may be narrowing of the orifice consecutive to inflammation of the whole glans, or to erosion of the lips of the meatus. In the fossa navicularis, the contractions often follow ulceration of the mucous membrane; they therefore belong to the class of cicatricial strictures, and are extremely dense, sensitive, and intractable.

All the varieties of constrictions at the meatus or in the fossa navicularis may escape attention for years, until the occurrence of some accident which may necessitate catheterism, when they are discovered by the surgeon.

Sometimes a small calculus is arrested behind the contracted external orifice, remains there for months or years, and attains very considerable proportions without being recognized by the patient. An interesting case of this kind was related to me last year by Dr. J. S. Davis, Professor of Anatomy, etc., in the University of Virginia. I shall give you a brief statement of it, extracted from a letter to Dr. Davis from the operator, Dr. J. B. Taylor:—On October 14th, 1864, Dr. Taylor received an urgent message to visit Mr. K., who was affected "with the gravel." He found the patient, a tall, emaciated man, thirty years old, in great agony; his penis was much swollen; the "glans," being as large as a man's fist, was red and sodden from the dribbling of urine. He declared that he had felt no pain nor known anything of his condition until the day before. His father, with whom he lived, knew nothing of it, except that he had had "the gravel" when a child. A calculus could be seen and felt through the meatus urinarius. Dr. Taylor applied lead water to the parts, and waited three days for the subsidence of inflammation; then slit the urethra, and with a pair of dressing forceps extracted the concretion, which was firmly embedded in the tissues. Much suffering followed the operation; on the next day the pain subsided, but the dribbling of urine continued. A silver catheter was then left in the urethra, and in a few days the wound healed. The Doctor carefully explored the urethra and bladder, but could find no other calculi. Dr. Davis, who has the calculus, writes me that it is phosphatic, and measures $4\frac{1}{16}$ inches in circumference.

If left to themselves these strictures will contract, and be followed by the same consequences as the deeper seated ones. Civiale, in his treatise on diseases of the genito-urinary organs, 1858, page 566, mentions three cases of narrow constrictions with urinary fistulæ, etc. In one there was rupture of the urethra, extravasation of urine behind the glans, and an abscess extending to the scrotum. In the second, rupture of the urethra had also occurred behind a stricture of the

fossa navicularis, then extravasation of urine, abscess, and, finally, several fistulous openings. The third case was a man 71 years old, whose meatus had been destroyed by a chancre: the glans was swollen, inflamed, and perforated by numerous small openings, which gave passage to the urine.

In October, 1868, I was called to a neighboring city, to see a man who had retention of urine. I found him moribund. Extravasation of urine had already taken place, the scrotum and perinæum being enormously swollen. At the external orifice there was a constriction, from chancre, through which but a small probe could be introduced. I divided the obstruction; there was another, anterior to the bulb, but I found no great difficulty in passing it with a No. 3 gum catheter. All this trouble had arisen from the stricture at the meatus, and the urethra had given way, under the pressure of the column of urine, at its weakest point, which was behind the deep-seated stricture.

Narrowing of the meatus is much more frequent than is generally supposed. An analysis, by Sir Henry Thompson, of 270 preparations, exhibiting 320 "distinct strictures," shows the proportion of constrictions near the outlet to be 17 per cent. of the entire number. In my own experience the proportion of strictures in that region to the entire number I have seen is much greater; it is at least 30 per cent.

There exists, in almost all of these cases, a localized chronic urethritis behind the stricture, which gives rise to some scalding in micturition and to a gleety discharge. There is also dysuria, proportionate to the degree of constriction; these symptoms, together with some reflex irritation at the neck of the bladder, lead the patients to consult their surgeons. Sometimes there are no evidences of disease, or they are so slight as to cause no apprehension. The trouble often escapes observation, on account of the defective methods of exploration employed by the majority of surgeons, or from entire want of exploration. The narrowest of the constrictions are generally situated at the external orifice, and there is no difficulty in distinguishing them. But those which are out of sight should be carefully examined after the manner described in Lecture I. When there is but a crescentic fold or a diaphragmatic membrane, a steel sound can readily be passed, no impediment is felt, and the surgeon dismisses the patient, saying there is nothing the matter. But the gleet continues, and the irritation at the vesical neck is still manifest. Therefore this mode of examination is of no value. The soft gum bulbous bougie is the best instrument for exploring the canal in its whole length, and you need never attempt the treatment of urethral diseases without having a complete set.

In the case of a crescentic fold or a thin membrane near the external orifice, the first catheterism may be sufficient to destroy either; the stricture is thereby divulsed, and a large sound introduced a few more times will be sufficient to effect a cure. But when there is narrowing of the orifice, or a well-formed stricture in the fossa navicularis, more energetic treatment is required. Here dilatation is not only unavailing, but gives intolerable pain, is followed by induration of the glans and greater subsequent contraction, and is sometimes attended with rigors and other constitutional symptoms. In its normal state, says Mr. Civiale, the meatus is the narrowest part of the urethra, and it is also the least extensible. It is not strange, then, that it should resist dilatation when diseased. Cauterization has been used with even worse results than dilatation. Divulsion is not to be thought of. Incision gives better results than any other known mode of treatment. This procedure was popularized by Mr. Civiale, who carried it out first, in 1823, to facilitate the passage of the lithotrite; and afterwards it became an established method of treating strictures in that portion of the urethra. The ancient lithotomists must, however, have resorted to it for the removal of calculi lodged in the fossa navicularis. Celsus gives directions how to make external urethral incisions for the removal of calculi embedded in the spongy portion, and doubtless encountered concretions in the fossa navicularis, and must have removed them by incision of the meatus. Some of the cotemporaries of Mr. Civiale seem at first to have made scarifications rather than incisions in strictures of the fossa navicularis and meatus, and used dilatation as after-treatment. They objected to Mr. Civiale's method because the uncontracted urethra, for a little distance behind the contraction, was divided; but Mr. Civiale claimed that this was necessary to insure success; and it now stands as a canon of urethral surgery, that not only the stricture, but from a quarter to half an inch of uncontracted tissue, in front and behind, should be included in the incision.

This operation can neither be called internal nor external urethrotomy. It partakes of the characters of both, for generally the meatus is divided, even if the constriction is in the middle of the fossa navicularis. It is done from within, but a portion of the cut is exposed to view. This, I think, is a sufficient reason why it should be treated of separately. It can be accomplished with a blunt or a sharp-pointed bistoury passed along the groove of a probe, or, as Mr. Civiale sometimes recommends, with a narrow, curved, sharp-pointed knife guarded by a small ball of wax, but he prefers to use the instrument (Fig. 15) already familiar to you, and

FIG. 15.

which, as you know, is similar to Frère Côme's "lithotome caché," reduced in size. I give you, in nearly Mr. Civiale's words, the description of the operation. The patient may be placed standing, sitting, or recumbent. The operator seizes the penis with the thumb and index of the left hand; with the right he introduces the urethrotome to the depth required, viz., about one-third of an inch beyond the stricture, opens the blade, and by a rapid traction cuts the stricture along the floor of the canal. He does not think it good practice to make very free incisions, as he fears that a fenestra behind the glans may result, but thinks it is better to be content with a moderate incision, which may be repeated in a few days. After such a procedure, he says, the diseased tissues may become softer and less resisting than they were at first, and cosenquently the second incision can often be dispensed with. I do not agree with Mr. Civiale in this respect, and prefer to make at once a free incision—just short of hypospadias—so as not to be obliged to employ the knife a second time, for the patient is very likely to object to it, even though the pain be very slight. The free division, if judiciously practised, will not generally be followed by any untoward result, and besides, it allows for the little contraction which occurs after cicatrization.

When the external orifice is too narrow to admit the urethrotome, I first make an incision with a small, straight, probe-like, beaked bistoury.

Rarely more than one incision is necessary, and that usually along the floor of the urethra.

Mr. Civiale quotes Dr. Payan as having, on several occasions, made two lateral incisions, and as proposing to add a second blade to the urethrotome in order to make two incisions at once, as in bilateral lithotomy. This plan answers well in cases of hypospadias, where the single inferior incision is impracticable. I have had occasion to adopt this practice in one instance. A young gentleman who had been suffering from a persistent gleet was also affected with a congenital hypospadias which had been increased in extent by a chancroid. His medical attendant had introduced instruments to No. 8, but with no benefit. The edge of the abnormal orifice was very thin and inflamed, and there was, at about one-eighth of an inch within, a stricture which had become very irritable. An inferior incision would only have made matters worse, so I made free lateral cuts, first on one side, then on the other, with Civiale's bistouri-caché, and was able to pass No. 18. The case terminated in every way satisfactorily, and there was no recontraction three years after.

Fig. 16.

Figure 16 is a diagram illustrative of the operation, with a double instrument, for stricture behind the thin edge of an abnormal external orifice.

Another exceptional case—requiring an incision along the upper instead of the lower wall—came under my observation last September. There was hypospadias, the orifice being at the base of the glans (Fig. 17 *c*), and admitting No. 7½ (English scale)

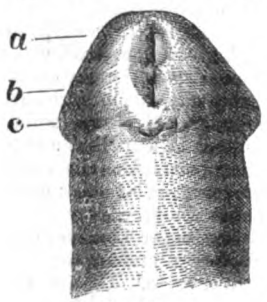

Fig. 17.

bulbous bougie, and another opening somewhat smaller (*b*), which was the mouth of a canal one inch in depth, along the upper wall of the urethra. There was a slit or depression (*a*) at the normal situation of the meatus. In this instance I passed a small bistoury, guided by a grooved probe, into the cul-de-sac and cut open the canal, so as to give it and the urethra a common outlet, and was able to pass No. 16 sound. The object of the operation was to facilitate the passage of large instruments to maintain the patency of a stricture, in the perineal region, which had been treated by external incision.

I have employed the various instruments indicated a moment ago, but prefer the bistouri-caché. As beginners may find this instrument too expensive, I have asked Messrs. Tiemann & Co. to make a cheaper one, which will answer the same purpose. This urethrotome may commend itself to you by its simplicity. It is shaped like an ordinary pair of surgical scissors, but has only one, outer, cutting edge, which is guarded by the other blunt blade when closed for introduction into the urethra. It is less than half the size of the bistouri-caché, and can be used with the same precision as Mr. Civiale's instrument.

The hemorrhage which follows this operation is generally inconsiderable, even when a very deep incision has been made. In a few cases it has recurred obstinately after each catheterism, for a week or ten days, but could readily be arrested by moderate lateral compression from without.

The operation is done so quickly that the patient seldom complains of much pain.

In two cases only have I encountered infiltration of urine (at the extremity of the prepuce),—Case I., Lecture I.; Case VI., Lecture III. When the frænum extends to the lower commissure of the lips of the meatus, make the incision a little to one side, or else divide the frænum from its attachment with a pair of scissors, and this trouble will surely be prevented.

The after-treatment is of the simplest kind. The retention of a catheter, long or short, should be avoided, though it has been recommended by high authorities. Professor Van Buren was in the habit of using a silver canula one-quarter of an inch in diameter, three inches in length, open at both ends, which was worn for forty-eight hours; but he was soon convinced of its uselessness, and gave it up several years ago.

Sir Henry Thompson advises the introduction of a plug of dry lint as large as a No. 12 instrument, this to be passed in one inch and replaced in a few hours by another, previously oiled. I found these plugs too irritating to be well borne, and discarded them long since. The introduction of a large-sized sound every third or fourth day for five or six weeks is generally all that is required.

As patients are often obliged to go and attend to their avocations immediately after the operation, I use a device, presently to be described, to prevent soiling of the garments. A very thin pledget of dry lint is introduced into the urethra as far as the cut extends, so as to prevent adhesion of the raw surfaces, and is retained by a strip of adhesive plaster one-third of an inch wide and about two and a half inches long, applied to the glans penis in the manner indicated (Figs. 18 and 19). The prepuce is then drawn forward and

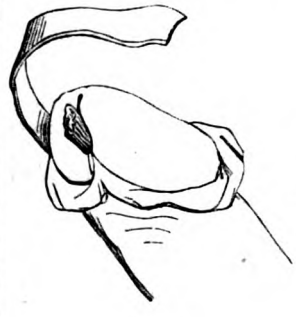

Fig. 18.

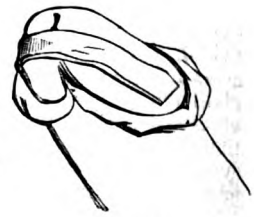

Fig. 19.

makes an excellent covering for the dressings. In this manner sufficient lateral compression is made to pre-

vent hemorrhage, and as it covers only half of the meatus, micturition is not interfered with. If it gets wet and loose, the patient can replace it by a fresh piece. The lint is changed at the end of twenty-four hours, and no dressing is required after two days, when granulations begin to sprout. The first time the patient urinates he complains much of scalding, but this subsides as soon as the urine is rendered bland and unirritating by the free use of diluents.

The object of the operation, in cases where the stricture is not narrow and gives no trouble, is to facilitate the passage of instruments for dilating deeper-seated constrictions. I have long been in the habit of dividing the meatus whenever a No. 12 sound could not be introduced without putting the parts upon a stretch and giving rise to pain. The operation causes less suffering than a sound which over-distends the orifice. I encountered seventeen cases of stricture at the meatus and in the fossa navicularis, which had to be incised, out of thirty-two cases of deep constrictions treated by divulsion; twelve out of fifteen cases treated by internal urethrotomy, and fifteen out of twenty-nine treated by the external perineal division. I am seldom able to carry ordinary dilatation of deep strictures of the urethra to the degree required without having previously divided the external orifice. Civiale has probably resorted to it more frequently than any one else; from 1823 to 1858 he had performed nearly three thousand operations with the best results.

Original Communications.

INCISED WOUND OF THE SUPERFICIAL FEMORAL—LIGATURE WITH SILVER WIRE.

DEATH ON THE TWENTY-SEVENTH DAY FROM DOUBLE PNEUMONIA AND VITAL EXHAUSTION.

By HENRY S. HEWIT, M.D.,

ONE OF THE SURGEONS TO CHARITY HOSPITAL.

On the morning of the 16th of April, 1869, I was summoned in haste to meet my friend Dr. J. W. Warner. Following the messenger with all possible speed, I found him sitting beside the prostrate, fainting, and exsanguinated figure of a young man, firmly compressing the femoral against the edge of the pelvis.

A small, but ominous and gaping wound, five inches below, directly over the track of the vessel, which was slowly filling and overflowing with purple blood, with occasional swifter impulse and crimson hue, as restless movement or relaxing muscle momentarily deranged the life-preserving pressure, revealed at a glance the nature of the surgical situation.

Diagnosis being obvious, brief consultation determined the operation, which I proceeded immediately to execute at Dr. Warner's request, with the additional assistance of Dr. L. P. G. Gouley, Physician to the Fever Hospital, Blackwell's Island, and Dr. James T. Synnott, now of the house staff of Bellevue Hospital.

Ether having been given, the wound was developed, the artery laid bare in the sheath, an irregular, oblique incision, one-third of an inch in length on its internal aspect, demonstrated, and silver ligatures applied, one above and one below the opening, twisted moderately tightly and cut off. The flow of blood, direct and recurrent, was effectually arrested, the external wound closed by silver sutures, lint wet in a weak solution of carbolic acid and diluted glycerine laid upon the line of coaptation, the limb swathed in cotton, and artificial heat supplied.

The pause succeeding these active and somewhat anxious proceedings gave an opportunity to elicit the following particulars:

The patient, German by birth, a Jew in religion and nationality, of sound constitution, correct habits, healthy and reputable parentage, aged nineteen, by occupation a butcher, while pursuing his vocation, on the morning in question, plunged his knife accidentally into and nearly through the inner portion of the right thigh.

The knife had been worn by repeated sharpening almost to a point, and the wound of the artery was probably inflicted by the heel of the blade, which retained its original width, in the act of withdrawal.

Copious hemorrhage followed, succeeded by complete syncope, and Dr. Warner arrived just as the swoon terminated, before bleeding to any great extent recommenced. The quantity lost was estimated by the father, also a butcher, and accustomed to slaughtering animals by the Jewish method, as not less than a gallon.

The condition immediately supervening upon the operation was one verging on collapse. Pallor and dampness of countenance, jactitation, feeble and gaseous pulse, coldness and numbness of affected extremity, precordial anxiety and distress.

Under the cautious and continuous use of stimulants and nutritives, reaction commenced and progressed in a tolerably satisfactory manner.

Warmth, circulation, and sensibility were restored to the thigh and leg in forty-eight hours, accompanied by considerable œdema.

The wound united by primary union for three-quarters of its extent. The lower and inner angle opened and discharged a moderate quantity of healthy pus. No secondary hemorrhage appeared, and the ligatures attached to the artery did not give any signs of irritation.

On the night of the seventh day, exposure to a draught of cold air was followed by a violent and prolonged chill, and immediately double pneumonia developed itself, together with excessive posterior congestion of the lungs.

The progress from this time was steadily and obstinately toward a fatal conclusion, but, owing to the medical skill and unceasing watchfulness of Dr. Warner, life was prolonged, with occasional hopeful glimpses of a happier event, for twenty days, when it expired with evidences of utter and complete exhaustion, coma, and apnœa.

It may, it would seem, be properly concluded from the foregoing details, that the original hemorrhage produced a shock from which it was impossible for the system to recover. The chill on the seventh day announced pneumonia, to which a high degree of hydrostatic congestion of the lungs, the result of the sudden anæmia following the excessive bleeding, predisposed them.

The metallic ligatures, twisted sufficiently tight to arrest the current of the blood without strangulating the coats of the vessel, amply sufficed for permanent occlusion.

The external wound, with the by no means unusual circumstance of suppuration and discharge through a portion of its extent, did well, and the limb was rapidly recovering its natural complexion, size, and appearance.

It is to be regretted that the scruples of the family and their haste for the interment, prevented an examination, and the preservation of what would undoubtedly have proved an instructive specimen.

129 East 29th Street, March, 1870.

Progress of Medical Science.

URIC ACID DIATHESIS AS A CAUSE OF BRIGHT'S DISEASE.—URIC ACID DEPOSITED IN THE KIDNEYS.—Dr. Gouverneur M. Smith exhibited to the N. Y. Acad. of Med., Jan. 6, 1870, an interesting morbid specimen, and spoke substantially as follows:—

In a paper read before this Academy in April last, I endeavored to illustrate the etiology of Bright's Disease by referring to 308 cases of the disorder as it has appeared in the New York Hospital.

I merely design this evening to revert to one or two points then alluded to, and to present a pathological specimen of unusual interest. Among other causes of Bright's Disease to which, on the occasion alluded to, attention was invited, were the *uric acid diathesis* and *saturnine impregnation*. A word on these topics, to show that minute foreign bodies, precipitated in the renal texture, may excite therein structural alteration.

Dr. Garrod some time since established the fact that in cases of *gout* urate of soda was deposited, not only about the joints, but also in the kidneys; as a sequel, for reasons hereafter to be mentioned, there was found the granular kidney. He further showed that workers in lead were peculiarly prone to the uric acid diathesis.

Olivier, in 1863, proved, by administering lead to dogs, rabbits, and guinea-pigs, that the metal itself would induce morbid action in the renal texture by becoming entangled in its meshes: to use his own words, as given by William Roberts, M.D., of Manchester, he could produce "incipient organic disease." His views were confirmed by the observation of cases of lead diseases coming under his treatment in the Charity Hospital, Paris, and were endorsed by Lancereaux and Danjoy. Several of the patients suffering with renal dropsy in the New York Hospital were workers in lead.

Lead may consequently induce Bright's Disease, either by its mere presence in the kidneys, or, by inducing the uric acid diathesis, may thus favor the formation of minute renal tophi.

During this winter term of service in the New York Hospital, two cases of gout came under my charge which were complicated with Bright's Disease. One case terminated fatally. The patient from whom this specimen was removed had suffered from gout about 16 years. The kidneys together weigh nine ounces, and are contracted and granular. The pyramidal portions are pretty thickly studded with small, hard granules, which are plainly visible to the naked eye.

I have exhibited this specimen to Dr. Clark, who was kind enough to examine microscopically the contained foreign bodies, and he pronounced them formed of uric acid. Chemical tests confirmed this opinion.

Dickinson, in his admirable monograph on albuminuria, in speaking of gout, remarks: "Dr. Garrod has pointed out, and I can confirm, that there occurs a deposition of urate of soda between the tubes, connected, that is, with the intertubular fibrous tissue of the gland. This portion of the organ becomes thickened by a sort of chronic inflammation; it contracts and compresses the tubes, and the granular kidney results. This description holds good, whether the gouty condition has resulted from intemperance, from the absorption of lead, or from any other circumstance."

It will be observed that, in the specimen which is exhibited, *uric acid*, and not urate of soda was discovered; possibly the salt may have been present in parts of the kidney not examined. An additional fact, it would appear, is thus established, viz., that uric acid, *per se*, may become fixed in the renal texture, and induce the same organic lesion as either metallic lead or the material ordinarily composing tophaceous deposits.

While uric acid, as has been stated by Roberts, "constitutes probably five-sixths of all renal concretions, and of vesical calculi, which have only recently descended from the kidney," I have not met with any statement that it has been found deposited in the nephritic parenchyma.

LEADEN COLOR OF THE TONGUE IN MALARIA.—For several years past, the peculiar color of the tongue in malarious fevers has attracted the attention of Charles O. Curtman, M.D., Prof. of Chem. in the Missouri Med. College. From a large number of cases carefully observed, with a view to ascertain the value of the appearance of the organ as a diagnostic sign in malaria, he has been led to publish in the *St. Louis Med. and Surg. Journal* the following deductions:—

In malarious affections the color of the dorsum of the tongue, as far back as the circumvallate papillæ, is of a bluish-gray tinge, somewhat resembling that of old sheet zinc or lead. It occurs in various degrees of intensity, giving the impression of a covering of greater or less thickness superimposed upon the epithelial surface, sometimes quite thin and transparent, at other times more opaque. Sometimes it has the appearance of being seen through a viscid mucous superstratum, at other times it is quite dry, but when present always has the peculiar leaden hue. It is not due to anæmic conditions, nor does it present exactly the same coloration as the tongue does in anæmia. No change of color has been detected in the same individual during the process of an intermittent fever through its different stages; but he has observed the same appearance in the cold, the hot, and the sweating stages, and could not see any alteration in it during the intermission. The color may be observed in equal intensity in the feeble, emaciated patient who takes an ague during the period of convalescence from exhausting disease. In some cases, however, though malarious fever was undoubtedly present, this color over the dorsum of the tongue could not be observed, but only around the edges and tips; but in those cases there was an opaque coating of the tongue, of a brownish-yellow or dirty white color, such as is usually denominated bilious. This presented the appearance of being superimposed upon the leaden covering, which it did not entirely overspread, but permitted to be seen at the tip and edges. This appearance was frequent in the remittent type. Not a single case has been thus far observed by him in which the tongue retained the clean, natural surface of perfect health. The leaden color disappears completely shortly after the entire cessation of the malarious symptoms, and serves as a valuable index of the perfect restoration to health. In several cases the leaden tongue has been observed without any concomitant symptoms which could fully establish the presence of malarious disorder, excepting a general malaise and lassitude, which so often are the prodromata of intermittent or remittent fevers. Dr. C. considers himself justified in predicting an attack of fever with some degree of certainty from the presence of the leaden tongue alone.

CHLORATE OF POTASH AND OPIUM IN THREATENED ABORTION.—The following case of threatened abortion averted by chlorate of potash and opium, published by Dr. John W. Trader, Sedalia, Mo., in the *Boston Med. and Surg. Journal*, may be of interest to the profession, in establishing the theory advanced by Sir James Y. Simpson, of oxygenizing the blood in those cases where an anæmic condition exists.

This patient had been married some six or eight years, and had miscarried at least once each year of her married life, at about the sixth month. In her last pregnancy she was anæmic and completely prostrate. The least exercise, and in fact the erect position, would often bring on uterine contractions, and sometimes hemorrhage. The chlorate of potash, in combination with opium, produced the happiest effects. Some few doses of iron were given, and some other incidental medication was resorted to, such as cathartics, citrate of magnesia, etc., but nothing which seemed to have the controlling influence of the chlorate. He used an aqueous solution of about the following strength:—

℞ Potas. chlorat. ʒ ij.
Elix. opii ..... ℥ ss.
Aquæ pur .... ʒ iv. M.

Sig.: Teaspoonful every three or four hours, as required. The opium alone was tried without the desired effect. She was compelled to keep her bed the most of the time, but at the end of nine months she was delivered of a full-grown, healthy child. Four months have elapsed and both are doing well.

On the Temperature of Children in Phthisis and Tuberculosis.—The diagnosis of consumption and tubercles in children is often very difficult. Every one knows how often they have been found on dissection, although not suspected during life. Children waste often with cough, and yet have no tubercles; and, on the other hand, they have tubercles often and do not waste, nor exhibit any chest symptoms. Sputa is uncommon in young children, and they do not have hæmoptysis. Percussion discloses little in many cases, because the tubercles are disseminated, and harshness is common to all childish breathing. Bronchophony, too, is not a sign to be trusted in children. Tubercular disease may be elucidated in children, Dr. Ringer thinks, by the use of the thermometer.

Wunderlich says the temperature in acute miliary tuberculosis conducts itself as follows:—

(*a*) At first, like the temperature in a catarrhal fever; later on, like an intense hectic fever.

(*b*) Just as in abdominal typhus.

(*c*) As intermittent fever.

Dr. Ringer seems to believe that there is a "continued elevation of temperature in *all* cases of tuberculosis. If the thermometer be used in the axilla it should be left in 20 minutes, according to our author. He takes the temperature in the rectum in most cases, and he introduces it two seconds, leaving it in from five to seven minutes. According to Dr. Finlayson, the value of the thermometer in the diagnosis of phthisis and tuberculosis in children is, that it gauges the fever. The importance of evening febricula as a sign of tuberculosis has long been known. Wunderlich says that phthisis without tubercles cannot be distinguished from tubercular phthisis by the thermometer.

Experiments on the Employment of Strychnine as an Antidote to Chloral.—M. Liebreich took three rabbits. With the first he injected two grammes of chloral beneath the skin of the back; with the second he injected fifteen grammes of strychnia; and with the third he injected two grammes of chloral, and the moment it commenced to show its effects, injected fifteen grammes of strychnine.

The first rabbit soon fell into a state of collapse; but the cornea appeared to remain sensitive, for irritation of it was followed by contraction of the lids. Death ensued in an hour and a half.

In the second rabbit, eight minutes after the injection the strongest tetanic spasms supervened, and death followed in twelve minutes.

The third rabbit, into which had been injected the same dose of strychnia which was fatal to No. 2, came to himself after a brief interval, from the injection of a similar dose of chloral as had been fatal to No. 1. He experienced no tetanic spasm, and at the end of an hour and a half got up, ran about, and ate as if nothing had happened.

Thus is established the strange fact that strychnine is an antidote to chloral, but *not vice versâ*. In fact, the rapidity of action of the latter agent produces poisoning before the chloral has time to act.

Ice in Chloroform Accidents.—Dr. Baillie, Surgeon to the Calcutta Native Hospital (*Med. News and Library*), is convinced that in cases of syncope from inhalation of too large a quantity of chloroform, there is no means upon which he should more rely to restore the movements of respiration, than the introduction of a *good-sized lump* of ice into the rectum.

This is much more easily effected than one would suppose; a little pressure with the ice being made over the sphincter causes it to relax, and the ice slips in, followed almost instantaneously by a prolonged inspiration, the precursor of natural breathing, and restoration of the heart's action. This measure, with only a *small* bit of ice, would, doubtless, answer equally well with still-born children.

On the Use of Electricity in Obstetrics.—Dr. de St. Germain, Surgeon to the Lying-in Hospital, has recently been conducting a series of experiments with electricity, as an obstetric agent, and he thus sums up the results in a communication brought forward at the Imperial Society of Surgery:—

1. We have not been able in any one case to produce uterine contractions, when they had not already appeared of their own accord.

2. Whenever labor had commenced, and the contractions were succeeding each other at intervals of from fifteen to twenty minutes, the application of electricity to the lateral walls of the abdomen produced a considerable amelioration of the uterine contractions after the lapse of only ten minutes.

3. We have also stated that each contraction excited by electricity was much longer and more painful than the others.

4. The dilatation of the cervix seemed to progress constantly with rapidity under the influence of galvanic excitement.

5. In all the cases the expulsion of the placenta immediately followed that of the child.

6. In two instances only we observed a slightly bluish hue on the skin of the child; but this might be attributed to cyanosis.

Dysmenorrhœa Membranacea.—Dr. F. Mandl, of Vienna (*Am. Jour. of Obstetrics*), believes the prognosis is generally unfavorable in *dysmenorrhœa membranacea*, not only with regard to conception, but also to its cure. The uncertainty and failure of our present treatment depend partially on the entirely unknown pathogenesis of the malady.

Chronic Inversion of the Uterus.—Prof. T. Gaillard Thomas, M.D. (*Am. Jour. of Obstetrics*), publishes "The History of Four Cases of Chronic Inversion of the Uterus," with the treatment employed. In a case presenting itself for the first time for treatment, he would use belladonna and the warm douche for a week, and then for another week, he would employ pressure by means of a caoutchouc bag filled with air and water. After this taxis, for a period not exceeding one or two hours, once, or at most twice a week, if the fundus were returned within the os, by closure of this after Em-

met's method. Having failed with these measures, *and not before*, he would resort to abdominal section. Instead of using a dilator of two limbs, he would employ one of four.

VIGILANCE TREATED WITH CHLORAL.—D. F. Lincoln, M.D., Boston (*Boston Med. and Surg. Journal*), recommends the hydrate of chloral (Markoe's) in cases of nervous prostration, the result of over-fatigue and anxiety, attended with sleeplessness. Given in 15 gr. doses on retiring at night, a full night's rest of seven or eight hours is insured, without any unpleasant results of any sort.

TREATMENT OF JAUNDICE.—Drs. White and Rochester, of the Buffalo Med. Association (*Buffalo Med. and Surg. Journal*), both agree that jaundice is caused by an obstruction to the free flow of bile into the intestine, and that this obstruction is most frequently produced by inflammation of the mucous membrane of the duodenum. The *former* sees no good reason for giving mercury. The alkalies are sufficient. He believes that the less we give cathartics the better. Counter-irritation over the region of the duodenum is beneficial. The *latter* gentleman uses calomel not as cholagogue but as a sedative, and finds the relative action of the drug to be induced, sometimes by small, and sometimes by large doses.

OPIUM A REMEDY IN RATTLESNAKE-BITE.—R. T. Short, M.D., reports a case of rattlesnake-bite in the *Medical Archives*, which was cured by frequent doses of opium. The patient was a lad of seventeen years, who had been bitten by an average sized prairie rattlesnake. Not having any *specific* for snake-bite he was compelled to rely on opium. Sixteen two-grain doses were given. The pulse, when patient was first seen, was 20 and very feeble. When the opium was discontinued, the pulse was 85. One remarkable feature in the case was, that the opium at no time exerted its characteristic soporific influence—perspiration was excited both times. The question naturally arises, does some principle in the opium prove antidotal to snake poison, or does it act by fortifying and replenishing the nervous system until the poison has spent itself?

INFLUENCE OF SECTION OF THE PNEUMOGASTRIC NERVES ON RESPIRATION.—Herr Voit of Munich (*The Quarterly Jour. of Science*), recently experimented on the effect of cutting the pneumogastrics on respiration. For the first few hours after section the amount of carbonic acid exhaled is the same as that before, then it diminishes. At a later period, when the tissue of the lung has begun to undergo a change, the quantity of carbonic acid diminishes rapidly, and that of oxygen is increased.

THE CHLORIDE OF POTASSIUM AS A SUBSTITUTE FOR THE BROMIDE.—The well-known physiological observations which have caused the action of the bromide to be attributed to the potassium, induced Dr. Sanders to inquire into the effects of the other combinations in the treatment of epilepsy. The chloride was found to have the same effect as the bromide, and thus far no case has been observed in which, the chloride having proved inefficient, the bromide afterwards had any more effect. No disagreeable secondary effects have been observed. It has been found that smaller doses of the chloride will suffice, in order to administer the same quantity of potassium, than when the bromide is employed.—*St. Louis Med. and Surg. Journal.*

SIMPLE PROCESS FOR DETECTING STRYCHNIA.—The *American Journal of Pharmacy* gives a process for this purpose, proposed by a Prussian chemist. It consists in saturating the suspected substance with ammonia, and allowing it to dry spontaneously; then heating it with a little amylic alcohol, after which adding a few drops of this liquid to sulphuric acid and bichromate of potash, when, if strychnia be present in the substance, the well-known coloration characteristic of that alkaloid will be obtained.

DYSTOCIA CAUSED BY HYPERTROPHY OF THE INFERIOR SEGMENT OF THE WOMB.—M. Bailly (Paris letter to the *Richmond and Louisville Medical Journal*) met with a case of this kind in a primipara, aged twenty, who presented nothing unusual until the time of delivery, when it was found that the lower segment of the womb was perfectly hard and thick. Pains set in, but at the end of the third day the os was only dilated to the size of a half dollar. Her general condition permitting no further delay, two incisions were made in the os, but forceps could not be applied, and craniotomy alone would allow the extraction of the child. Twenty-seven hours after the patient died, and the autopsy revealed peritonitis, with a quantity of pus and false membrane. Microscopic examination showed fatty degeneration of the muscular fibres and hypertrophy of the fibrous tissue.

PRESERVING VACCINE VIRUS.—Dr. A. W. Sueck has used the method of Dr. D. Prince for preserving vaccine virus. It is as follows: take a portion of common alum and place it upon a red hot stove until the water of crystallization is driven off. Of this dried alum fill half full a bottle of an ounce capacity. Envelop the vaccine seal in a piece of paper and tinfoil, and place it over the alum in the vial. Adapt a well-fitting cork, and cut off even with the top of the bottle. Seal air-tight with sealing wax.—*Chicago Medical Journal.*

HEART-CLOTS.—Joseph Jones, M.D., Professor of Chemistry in the Medical department University of Louisiana, New Orleans (clinical memoranda), in a valuable lecture on "Heart-Clots," states that the formation of heart-clots during life is very common in malarial fever. In fifteen post-mortem examinations he found them in ten cases; of the remaining five, one was a case of typhoid fever combined with remittent fever; another was a case of malarial fever of long standing, where the patient died of exhaustion; and in the remaining three no special examination for heart-clots was instituted.

In view of the rapid, feeble, intermittent pulse; disturbed, full, panting respiration; rapid, feeble, fluttering action of the heart; cold extremities, exhaustion of the muscular forces, stupor, wandering of the intellect, inability to control the muscles and acts of excretion; in view of the sudden onset of all these symptoms in malarial fever; in view of the size and structure of the coagula found in the heart and blood-vessels after death, in the cases presenting these symptoms; in view of the close correspondence of these symptoms with those characteristic of the deposition of fibrin in the heart and blood-vessels; in view of the observations of various physiologists and pathologists, we are justified in asserting that the fibrinous element of the blood may be deposited in the heart and blood-vessels during life in malarial fever, and not only give rise to a distinct set of phenomena, but cause death in cases which otherwise would not have terminated fatally.

THE IDENTITY OF THE EFFECTS OF JENNERIAN AND ANIMAL VIRUS.—M. Herard (The *Chicago Med. Journal*) has made a comparative study of animal and Jennerian (human) vaccination, in 493 new-born infants, and has been unable to detect any difference whatever between the effects of the two varieties of virus.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

THE RELATIONS OF PHYSICIANS AND APOTHECARIES TO EACH OTHER.

A GREAT deal has been said regarding the relations which should properly exist between apothecaries and physicians, and as we believe that a great deal more discussion must be had before the mutual rights can be consistently adjusted, we take a favorable opportunity for glancing cursorily at both sides of the general question. Viewing, however, the whole matter in a properly conservative spirit, we are forced to conclude that the wrong-doing is not altogether on one side; that one profession is perhaps as much to blame as the other. The lack of a disposition to acknowledge this has tended, in our opinion, more to widen the breach than perhaps anything else, and has caused real sound argument to degenerate into angry dispute. Both callings have their individual rights, which each in its turn is bound in a truly consistent spirit to respect. The profession of medicine must recollect that that of true pharmacy has, especially within the past few years, risen to a respectability and influence that have been commensurate with the increased requirements of science,—in a word, that there are a greater number of thoroughly educated pharmaceutists in our midst than ever before. This being the case, it becomes us to vote them a fitting amount of respect and consideration, and to counsel with them rather than abuse them.

We are convinced that the only way of bringing about a proper understanding between the two bodies is a disposition on the part of each not only to acknowledge the possession of individual rights, but to respect them in a practical manner.

In the first place, then, the pharmaceutist who adheres to his calling proper has a right to look to the physician for a reasonable pecuniary support. He is presumed to desire only such aid as his relations to the physician entitle him to, beyond which, as an honorable man, he does not care to go. His highest and truest vocation is that of a compounder of medicines, a practical chemist, and not a mere vender of drugs. But the question as to whether he can live by strictly confining himself to this particular branch is not a very difficult one to answer by the majority of such as have striven to do so. His prescription business, although remunerative enough as far as it goes, is not, in the main, sufficient to cover his necessary expenses and leave him a profit. If the profession of medicine maintain that the apothecary should not seek to make money outside, they should take the question seriously to themselves as to how this is to be prevented; and further, if it is in their power to aid him in his endeavor, it is to the interest of both that it should be done. It is certainly just that the physician at least place no obstacle in the way of its attempted attainment. If the pharmaceutist desires to restrict his business entirely to the compounding of prescriptions, the physician is bound to do all in his power to encourage him—he should, as a matter of principle, leave such part of the business entirely in the former's hands. But is this always done? We are forced to answer in the negative. Very many practitioners are prone to think that they are not bound by any obligations to the skilled compounder, and consequently hardly ever hesitate to prepare and sell their own medicines to the patient for whom they may be prescribing. This may be proper enough in thinly settled rural districts, where no apothecary is near at hand; but when the opposite state of things exists, we hold that it is radically wrong. The physician is no more by right a compounder of drugs than is the compounder a physician; and it must be conceded that each can operate to the best advantage, and do the greatest good to his patrons, by restricting his labors to his own legitimate sphere. This general principle of action is considered of so much importance that an amendment to the code of ethics of the American Medical Association, on the duties of physicians to each other, and to the profession at large, is proposed, in order that these requirements may be properly understood and practically met.

"The spirit of trade and of gain from merchandise should by all means be dissociated from the practice of a liberal profession, and it is important that practitioners should not allow their pecuniary interests to compromise their duties to their patients. Therefore, in cities and other communities where the services of competent apothecaries can conveniently be obtained, physicians should resign to them the whole business and profits of dispensing medicines."

The said amendment lies over until the coming meeting of the Association, and we cannot see what objections can be urged against its adoption. In our opinion this will be a decision against the proprietary right of physicians for drug stores, and compel them to choose between pharmaceutist proper and physician. If it can be proved that pharmaceutists are unable to gain a respectable livelihood by the prescription business alone, or by the manufacture of chemicals and pharmaceutical preparations, there can be no objections against the selling of perfumery and articles of toilet. In fact, we can see no impediment to the practice in any

event, as there is no tendency thereby to degrade either the profession of pharmacy or of medicine. When, however, there is a willingness to sell patent medicines, both callings are disgraced. We cannot conceive of any reasonable excuse for such a practice, sanctioned though it be by almost universal countenance. The profession of medicine, on its own behalf, has a right to object to this custom, and it is just that this objection should be respected, in so far that those who persist in the practice should not complain if they be denied the usual prescription business.

Again:—The most pernicious practice of prescribing from behind the drug counter should be entirely abolished. Any one who does not frequent the apothecaries' stores, and who is only in the way of hearing one side of the question, may well be astonished to learn of the great prevalence of this imposition. The establishments in which there is an exception to the rule can be numbered only by scores. We admit that there is a great temptation to do it, offered by the community itself; that the otherwise conscientious apothecary is coaxed to "give something," and many inducements held out to him by his patron; but this is no reason why he should yield and do what he knows to be wrong, not only to the would-be patient, but to the physician, whom the said patient would otherwise probably consult. These knights of the pestle do not pretend to take any responsibility, and yet appear to assume as much as the skilled and qualified prescriber. We have known these pretenders to ignore entirely the presence of a physician, and in the most insultingly defiant manner advise the patient as if they had an unquestioned right so to do. This is certainly not the way to foster a good feeling between apothecaries and physicians. We will take occasion here to introduce an extract from a letter, which we select from a file of similar ones, in order to give some of our readers, who may not be well informed on the subject, an idea of the amount of discretion and ability which many of these prescribers possess:—

"I am convinced, from personal experience, that this practice (prescribing) of our city druggists is very much on the increase, and that for some unexplained reason they at the same time enjoy the patronage of the most extensive and influential practitioners in the neighborhood. As for the advice that the poor patient gets from the druggist it is *nil*, and as to medicine it will be given in unlimited quantities as long as it is paid for. I have chanced to be in the stores of some of the prescribing druggists, and have known them, especially in cases of supposed venereal diseases, be satisfied with the assertion that the patient had the 'syphilis, or gonorrhœa,' never ask a question, or make a remark (except perhaps a joke as to the origin of the disease), nor care to look at the case, but at once make up a mixture, for which two or three dollars is charged, and a day appointed for another interview. On one such occasion, the druggist, not knowing that I was a physician, after the patient left, was asked by me, with a show of curiosity, what the man complained of? The answer was, 'The pox, I suppose.' In answer to the question as to what had been done for him, the reply was, 'I gave him some sarsaparilla and copaiba to drink, and "black wash" as a lotion.' 'Do you think that will cure him?' asked I. 'Well, it may, and it may not,' replied he; 'and if it does not, he can go to a doctor. There is certainly no harm in trying to do something for the fellow first.'"

This may be an exceptional case, but if it is, we are cognizant of some that will equal it in ignorance, presumption, and dishonor.

The proprietorship of prescriptions has, in its turn, given rise to a good deal of discussion, not to say hard feeling, but our readers know enough of this to render it unnecessary for us to present the different aspects of the question in its relation to the rights of apothecaries on the one hand, or those of physicians on the other.

In the present state of affairs, although the physicians are not by any means faultless in their many relations to the pharmaceutists, it must be admitted that it is much easier for the former to submit to the reciprocal code than the latter, especially in this matter of prescribing, to which innovation the profession, as a body, cannot and must not submit. We cannot, however, doubt that the rapid increase of their number will, before long, enable the "good men and true" in the ranks of pharmacy to rule out, by force of example, many of the objectionable practices of their brethren, when they will find that physicians will be only too ready and willing to do their share in the great work of mutual reform.

An excellent suggestion is made by an English druggist in relation to the dispensing of poisonous substances. He proposes that, in addition to the word "poison," the labels should have printed on their margins the appropriate antidotes for each class of poisons. A bottle containing a mineral acid, for instance, would have on its label:

"POISON!

"If taken by accident, give (mixed with water) chalk, or soap, or whiting, or ceiling-scrapings."

Similar labels might be printed for the various classes of deadly drugs.

Hydrophobia.—Dr. Buisson recommends one of the most simple remedies, being at the same time preventive and curative. He says, when a person is bitten by a mad dog he should take seven steam baths, one each day, Russian, for instance, of fifty-seven to sixty-three degrees. When the disease makes its appearance only one steam bath is necessary, raising the temperature hastily to 50 degrees centigrade, and afterwards slowly to 63 degrees. The patient should be well confined to his room until completely cured. He says he cured himself by these means, and more than eighty persons besides.

Nélaton.—M. Nélaton, we regret to hear, is said to suffer from heart disease, and will relinquish practice.

Reviews and Notices of Books.

I. Fourteenth Annual Report of the Trustees of the State Lunatic Hospital at Northampton, Mass. October, 1869, 1870.

We learn from this very complete report of Dr. Earle, that the past has been a year of great prosperity and improvement in the institution under his charge. Five hundred and ninety patients have been treated during the year—254 male, and 336 female—of whom 49 have recovered, 51 improved, 63 unimproved, and 25 died—total 188; daily average number of patients, 405. This hospital is the last erected by the State for the insane, and has always, hitherto, been the receptacle for many of the chronic incurable cases from the other two similar hospitals in the Commonwealth. Hence the relatively smaller number of recoveries.

We are pleased to observe the high importance always attached to *moral treatment* by Dr. Earle, especially out-door exercise, which, as he truly states, "modifies the action of both the intellectual and moral part of our being." He places "manual labor" at the head of all remedial agencies for the cure of insanity, and in no other year do the statistical records of this hospital show so large a number of the patients employed in work as in that just come to a close. In all the departments of labor the majority of the workers are State patients, although many of the town patients and boarders are also employed, as a matter of choice by the inmates. A detailed description is given of the "Exercises and Entertainments, Reading, Recreation, and Amusements, the Farm," and its products, together with other interesting matters, all going to show that there is no Insane Hospital in the United States more skilfully and successfully managed than that of Northampton.

II. Triennial Report of the Superintendent of the Tennessee Hospital for the Insane for 1869. By W. P. Jones, M.D.

The whole number of patients treated in this institution during the last two years has been 514; of whom 220 have been discharged, and 294 remain; 100 have been cured, 48 improved, 10 unimproved, and 42 have died. We regret to see it recommended by the Board of Trustees to erect another asylum of equal size on the present hospital grounds; inasmuch as *segregation*, not *aggregation*, is the true policy, as recognized by nearly all writers on insanity at the present day; and moreover there is already too little farming land attached to the present hospital for the wants of the patients.

The superintendent very wisely recommends a judicious system of religious worship in hospitals for the insane, as exerting a very beneficial influence on the minds of the patients. Separate hospital accommodation is recommended for the criminal insane, and in 1865 a separate building was furnished by the State for the accommodation of the colored lunatics. We regret to observe that, owing to an injury received from one of his patients, while in the discharge of his duty, Dr. Jones has felt obliged to resign his situation as superintendent, which he has filled with great honor and usefulness for over seven years past.

III. Annual Report of the Managers and Superintendent of the Western Pennsylvania Hospital for 1869. Pittsburg, 1870.

This flourishing institution is located at Dixmont, near Pittsburg, Pa., and under the superintendence of Dr. Joseph A. Reed, with Dr. J. B. Ewing as assistant physician. Four hundred and ninety-six patients have been treated during the year; deaths, 39; 46 restored, 42 improved, 32 unimproved. At present there are 334 patients in the hospital—195 males, 139 females. With only 200 sleeping apartments, the hospital has evidently been overcrowded during the year, and has probably only been saved from serious deterioration of health among the inmates, and an excessive mortality, by thorough ventilation by "*the fan.*" Of the patients admitted during the year a large proportion have been *chronic cases*, which could have been as comfortably provided for, and at a tithe of the present expense, in smaller and cheaper buildings, on the *cottage system;* and yet, as Dr. Reed remarks, "it is this large and often neglected class that have taken possession of the hospitals of the State." Over $9,000 worth of farm products were raised during the year 1869, which speaks well for the industry and labor of the patients.

IV. Report of the Pennsylvania Hospital for the Insane for the Year 1869. By Thomas S. Kirkbride, M.D., Superintendent, &c.

This institution stands second to none in our country for the skill and success with which it is conducted, and the scientific attainments of its accomplished head. So distinguished and popular is Dr. Kirkbride in the management of the insane, and so humane and kind is his deportment towards this unfortunate class, that every year an increased number of patients voluntarily resort to him for treatment; especially those whose minds have been liberally cultivated, but whose faculties have not yet been so much perverted as to render them unconscious of mental disorder; while they are sensible of its threatened dangers, and fully alive to the importance of early treatment. We have known several such individuals, who have been fully restored after a short residence in the Pennsylvania Hospital, and who speak with enthusiasm of the many pleasant features of their domicile there, and the benefits they have received from the hands of its enlightened and humane superintendent.

The great advantages of an extended classification, and of separate buildings for the two sexes, have never been more satisfactorily exhibited than in this model institution. For example, there are sixteen separate classes of patients for each sex, which gives opportunity to bring into association only those who will be most likely to be beneficial, rather than injurious, to each other; and this really is the basis of all rational treatment. But it is an advantage enjoyed in very few of our insane hospitals; and so injurious are the effects of indiscriminate agglomeration of all kinds of cases, that it is with extreme reluctance that many persons consent to send their friends to a lunatic asylum; and especially is it a powerful argument for separate institutions for the recent acute cases, and those of a chronic character.

Were all our asylums placed on the footing of the Pennsylvania Hospital for the Insane, and managed with equal judgment and skill, there would be little foundation left for those changes and reforms which have recently been advocated and recommended.

This hospital was opened in 1841, since which time 5,535 patients have been received, and 5,222 discharged, leaving 313 under treatment. The greatest number of admissions have been between the ages of 25 and 30; the next between 20 and 25; and next, 35 and 40; 10 have been admitted over 80, and 33 between 75 and 80; 79 between 70 and 75; 102 between 65 and 70; 196 between 60 and 65. Of professions, 377 have been farmers, 287 merchants, 244 clerks, 59 physicians, 59

lawyers, 32 clergymen, 91 shoemakers, 401 no occupation. Dr. Kirkbride very truly remarks that "the public should learn that it is not only humanity and practical Christianity for the State to make suitable provision for all the insane that require hospital accommodations, but that there is real economy in such a course; for even if patients were treated at the highest rate of board for a few weeks or months, and cured, it must be much less costly than would be a life support of the incurable, and of those, perhaps, dependent on him, on the lowest scale of subsistence, to say nothing of adding to the wealth of the State by changing what was only a consumer into an active producer."

This is very true, but the difficulty in the case is, that the States are unable, even if willing, to provide for all their insane (1 to 700 of the population) on the magnificent footing of the Pennsylvania Hospital, costing originally $2,000 per patient, and $7 to $8 per week for board.

The problem now undergoing discussion, and which is about to be tested by the State of Illinois, is whether the vast majority of the insane—the quiet, chronic cases—cannot be comfortably provided and cared for on a more economical plan, which, while it furnishes the advantages of domestic home-life, in plain, inexpensive dwellings, with necessary superintendence, will also supply all needful facilities for regulated labor, so essential to the bodily and mental welfare of the insane.

V. Biennial Report of the Superintendent of the Insane Asylum of California. 1869. By G. A. Shurtleff, M.D., Superintendent.

This is the 17th annual report of this Institution. It is under the charge of two physicians only. It numbers 920 patients, and the whole number treated in 1869 is 1,335; deaths, 159; ratio of recoveries, 46 per cent.; and of deaths about 12 per cent. The chronic and incurable cases never leave the asylum during life. The vast majority of the cases are such as are usually found in county houses and jails. *Consumption* has been the most frequent cause of death; next in order, *marasmus, paralysis, debility, epilepsy*, etc. The institution is shamefully overcrowded, a heterogeneous assemblage of idiots, *epileptics, imbeciles, criminal insane*, etc.

The insane, it is known, increase at the rate of 10 per cent., and yet California has made no provision for any further accommodation for this class for nearly 20 years, and its only hospital has gone on increasing its inmates at the rate of 60 or 70 every year, although always overcrowded even from its establishment.

To relieve this overcrowding, the superintendent states that a *cheap cottage wooden* block of buildings has been erected during the past year, capable of accommodating 135 patients, and he thinks "*these light detached tenements are more agreeable to most patients than the wards of our ordinary high massive asylum buildings. They feel less secluded from the world; they like to be near the earth; they do not feel so far removed from liberty, as one would feel less oppressed, confined in an ordinary domestic apartment than he would in a tower.*" "The plan answers every purpose for the accommodation of the milder and non-destructive cases" (which make up the vast majority), and "room can at any time be thus furnished at the rate of less than 100 dollars to the patient, whereas the rule is $1,000 to the patient for the expense of constructing complete separate establishments for the insane" (p. 25). And yet, although Dr. S. admits that the quiet and harmless chronic cases require less room, and fewer attendants, and less medical attention, than the violent and destructive acute cases, and that buildings suiting them far better can be erected at *one-tenth* of the cost of the large asylums, still he is opposed to any change in the present system, and very inconsistently argues that the chronic cases can be as economically treated "in a complete institution for all, as in one for a particular class." In regard to "humanity," which seems to be a great obstacle to any change or improvement in the mind of the superintendent, after admitting that the "cottage *block*" is far better liked by the patients than the "massive asylum building," and far more congenial to their feelings, we think what is said on this point somewhat superfluous. In all insane asylums the noisy, violent cases are separated as far as possible from the quiet, chronic cases; if they were to be removed a little farther still we do not suppose any great harm would come from it.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Stated Meeting, March 21, 1870.

Dr. George T. Elliot, President, in the Chair.

REPRODUCTION OF BONE.

Dr. Wm. R. Whitehead read a paper upon this subject. Assuming that the conditions which regulate bone growth, could we fully discover them, would be found as constant in their action as those which govern the phenomena of inorganic nature, the speaker proceeded to give his views of the true method of investigation to be pursued, and to review the history of opinion upon the subject of osteogenesis, touching also upon the general history of experimental research in medicine and its cognate sciences. It was important to seek for the minor laws that modify the working of the more general ones, producing perturbations which, whether seen in the growth of a cell, in the formation of a crystal, or in the motions of a planet, will prove, when their laws are discovered, to be not fortuitous, but regular. And to aid in these researches, it was important to bring the results of a broad generalization to bear upon each limited department of study.

To Duhamel, in the last century, when France was the theatre of the highest intellectual activity, was due the discovery of the property of the periosteum to reproduce bone. The theory, suggested by his studies in vegetable physiology, he established by experiment. It was opposed by his contemporaries and rejected by Bichat and Scarpa, who for a time held almost undisputed sway over medical opinion. Later, Dupuytren admitted the action of the periosteum in forming the "provisional callus"; but it was only about a century after Duhamel's discovery that it was forced into general recognition by the efforts of many investigators, prominent among whom was Flourens. At present Sédillot is the leading opponent of the doctrine that the detached periosteum has the power to reproduce bone, maintaining that the only way of insuring regeneration, in cases of necrosis, is to scoop out (*évider*) the bone in such a manner as to leave its outer layer still adhering to the periosteum. He has been ably refuted, and the efficacy of subperiosteal resection fully established, by Holmes and many others. Among the surgeons in this city whose experience upon this point would seem to be conclusive, may be mentioned Dr. James R. Wood.

But the repair of bone is not left dependent upon the periosteum alone. The medullary tissue has a similar power, which, as Goujon has conclusively shown, it may exhibit after transplantation into vascular parts, especially in early life, when it contains an abundance

of calcareous salts. But it is far less likely to produce bone than is the periosteum, under similar conditions, and the bone produced is soon absorbed, while that originating from periosteum is apt to be permanent. As to the so-called medullary membrane, or endosteum, its functions, whether of reproduction or absorption, cannot be regarded as settled; and indeed its very existence is in dispute.

Although the medullary tissue stands next to the periosteum in osteogenetic power, yet it shares this with nearly all cellular and fibrous tissues, and even muscular tissue may become ossified under favoring conditions. These conditions would seem to be chiefly long-continued or repeated irritation, in connection with "a perverted assimilation of the calcareous salts of the blood." The presence of some of the proper osseous tissues in a state of irritation is also regarded by Ollier as conducive to ossification of the neighboring parts.

The effort to obtain reproduction of bone by transplantation of periosteal flaps (as distinguished from subperiosteal resection), so successful in many of the experiments upon animals, has not commonly met with the same success in man. Still, its satisfactory results, under good conditions, are sufficiently numerous to warrant its recognition as an important surgical procedure, likely in the future to receive a wider application. At present, perhaps the best illustrations of its value are to be seen in Langenbeck's operation for closure of cleft of the hard palate, known as muco-periosteal uranoplasty. The speaker had—in two cases of this operation which he had published—convinced himself that the cleft in the palate might thus be closed by a growth of new bone.

In conclusion, Dr. Whitehead related three experiments of subperiosteal resection which he had made upon rabbits, and exhibited the specimens showing their results.

Dr. J. C. Nott said that, some thirty years ago, Dr. Toner, now of California, then a young man commencing practice, had published several cases of onychia, in which he had removed the phalanx, leaving the periosteum, and obtained a reproduction of the bone. Impressed by these cases, the speaker had himself followed this practice ever since, and with success. He had heard that old Dr. Dudley was accustomed to treat onychia in the same manner. In a case of necrosis of the upper jaw he had, in removing the bone, left its periosteum in situ, and the bone was regenerated.

Dr. Sayre had from his earliest practice removed phalanges in the manner above described, which he had been taught by Dr. Dudley. It was very important, in such cases, to dress the finger, during the process of healing, so as to preserve its normal shape; otherwise the nail would become hooked over, or some other deformity result. One of the speaker's sons had smashed his finger throughout its whole length, so that at first amputation seemed unavoidable. But by careful preservation of all the periosteum almost complete reproduction of all the phalanges was secured, and the finger was now serviceable, though somewhat shorter than its fellows. The doctor had resected subperiosteally four and one-half inches of the femur of a young man. The bone was completely reproduced, the limb equal in length to the other; and the lad had last winter won a prize in a skating match.

Dr. Chadsey related a case of necrosis of the entire tibia, which was removed as a sequestrum; new bone having formed around it firm and serviceable, though at first large and misshapen. It gradually became reduced to about the natural size. A patient of his had been kicked by a horse above the eyebrow, severely comminuting the outer table. In removing the pieces of bone, the periosteum was left attached to the skin; and the lost bone was restored with no depression or deformity.

Dr. Biggins referred to two cases of necrosis of the lower jaw, from gangrenous stomatitis in children, which had come under his care at the Nursery Hospital, Randall's Island, in 1850. In one of them he had resected the bone from the canine tooth to the angle of the same side; in the other, from the canine tooth to the angle of the opposite side. The periosteum was carefully left in both cases, and in both the part removed was reproduced, though of course without teeth or alveolar process.

The President said that in some cases of pelvic deformity which would otherwise necessitate the Cæsarean section, it had been proposed to resect portions of the pelvic bones so as to permit of delivery, trusting to the undisturbed periosteum to restore the loss. Osteophytes, when they occurred in the pelvis, were most apt to be seated along the linea ilio-pectinea, and might be a cause of rupture of the uterus during labor. He referred, also, to the cases of incurable deafness produced by the sealing up of the external auditory canal by a bony growth.

The Society adjourned.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

MEDICAL RECOLLECTIONS OF ENGLAND IN 1868.

Dr. Bradford S. Thompson, of New York, read a paper with the above title, of which the following is an abstract:

It was in the month of May that we left New York, in the good *packet-ship* Columbia, of the famous "Black Ball Line," bound for Liverpool, a commercial city like our own, with great natural advantages, but, in the words of Dr. Carpenter, "cursed with a neglect of the sanitary laws, cursed also by drink and debauchery to a greater extent than any other town in England. Being the most criminal as well as the most unhealthy city on the island, it is called the *Plague-spot on the Mersey.*"

For the benefit of those who desire to take a trip across the briny ocean for the restoration of health, it is proper to remark that a good sailing-vessel is superior to an ocean steamer in going to the eastward from the first of May until the first of September, for the following reasons:—The westerly winds prevail generally at this season of the year, and are conducive to short passages. Passengers avoid the nauseating, oily smell emanating from the machinery, which helps to originate sea-sickness. The state-rooms are more commodious, and the cabins less cramped; and, contrary to our expectations, a sailing-vessel under a steady breeze rolls less than the prevailing and popular screw-steamers.

The terrible scourge—*sea-sickness*—reminded us of the true and quaint remark made by the living "Nestor of the Presbyterian Church," Rev. Samuel Hanson Cox, D.D., who, several years since, while crossing the Atlantic, said: "Old ocean is one grand dose of ipecac."

The ancient town, as it is called there, of Liverpool has a population of about 500,000 inhabitants, while at the beginning of the eighteenth century it only laid claim to 5,000. Respecting the etymology of its name various opinions have arisen; but, although the

subject still remains a matter of doubt, it is generally believed to be derived from a fabulous bird called the *Liver*, and this accordingly figures in the arms of the town.

Everything in Old England seems to have been built to stand for ages. The pavements, buildings, cabs, and even the inhabitants, all partake of this solid character.

Liverpool is protected by hills from the cold withering north-north-east winds; and the climate, though humid, is more equable than in most other places of the United Kingdom; the sea-breezes temper the heat of summer, and the cold of winter is usually from six to eight degrees below that under the same latitude on the eastern coast. The average temperature ranges from 41° to 61°.

The charities of Liverpool are ninety-six in number, and munificently supported, many of the edifices devoted to charitable purposes being really handsome.

The Royal Infirmary, an extensive and noble edifice, is one of the finest buildings of which Liverpool can boast. Thomas Inman, M.D., the quaint and sound practitioner, is one of the attending physicians of this institution, which reminds one of the late New York Hospital.

The Northern Hospital is the largest of its kind in that city, and is on the whole one of the best arranged, most convenient, and most comfortable in the kingdom. This hospital answers to Bellevue Hospital, in New York City, in its general arrangements and standing.

While alluding to hospitals it is proper to remark that the hospital in Norwich, England, is said to be the finest, cleanest, and best-managed institution in Great Britain.

While on a visit to the quiet village of Hale, about ten miles from Liverpool eastwardly, a tomb of a celebrated *giant* named John Middleton, called the *Child-of-Hale*, was pointed out. He was born in 1758, and was possessed of extraordinary strength; his height was nine feet and three inches, and his hand was seventeen inches long. "The Child-of-Hale Inn," which is near the house which he inhabited, has a sign representing him in appearance and dress.

Manchester, thirty-one and a half miles from Liverpool, is the great cotton manufacturing mart of the world—styled the capital of the manufacturing district of Lancashire—where merchants of all nations flock to buy the fabrics of her manufacturers and merchants. This city has a population of nearly half a million of inhabitants, but presents a better appearance than Liverpool on account of its high and inland situation. The buildings, as a rule, are finer, the streets are wider and more regularly laid out, and the inhabitants more sociable.

It boasts of a noble Infirmary devoted to the sick, which is situated opposite the Queen's Hotel, on Queen's Square, and as we were professionally interested in everything connected with medicine, we gained an introduction to the chief surgeon of that hospital, and can vouch for the great reputation which it holds in the public mind. William Roberts, M.D., Lecturer on Medicine in the Manchester School of Medicine, and author of the "Practical Treatise on Urinary and Renal Diseases," is one of the attending physicians to this Infirmary.

In front of this Royal Infirmary the statues of John Dalton, a chemist of world-wide fame, and James Watt, the great inventor, stand as remembrancers to the rising generation of the parts which those distinguished men played in life.

On Saturday evening, in the month of June, we arrived at the *Charing Cross Hotel*, finished in 1865, an immense structure situated on the busy thoroughfare called the "Strand," in the open space called Charing Cross, which takes its name from the old village of Charing, where stood a cross erected by Edward II. A statue of Charles II. now stands on this spot, and, being a central point for the west end of the town, is a desirable place to stop at. St. Paul's Cathedral, Nelson's Monument, The Mitre (where Dr. Johnson used to delight to take his chops, tea, and ale), Houses of Parliament, and Westminster Abbey are all within a stone's throw of this hotel.

While alluding to *beer*, we remark that the amount used yearly in Great Britain and Ireland amounts to 728,200,000 gallons. It is estimated that the quantity of the beverage consumed in Europe each year would require to contain it a canal five English miles in length, fifty feet deep, and two hundred feet broad. At present England alone spends $100,000,000 a year in beer, and her expenditures for drugs used in adulterating beer and other intoxicating beverages are enormous.

The renowned *Kitcat Club* had its first assemblies at a house in Shire Lane, still standing, near Temple Bar; it was occupied by a pastrycook named Christopher Kat, famous for his skill in making mutton pies, a dish from which the club itself took its name.

"A Kitcat is a supper for a lord," says the prologue of a comedy of 1700. This club was the great Whig club of Queen Anne's time, and originally was composed of thirty-nine members. In later days it numbered the greatest wits of the age. The poet of the Kitcat, *par excellence*, was Sir Samuel Garth, the physician and friend of Marlborough. He is poetically known in the days of King George II. chiefly by his "Dispensary," a satire upon apothecaries. He was a jovial member and a witty man. One night being at the club, and in love with the wine and the company, he had completely forgotten the fifteen patients whose names appeared on his list of the day, but whom he had so far left unvisited.

When it had become too late to call upon them, he excused himself to his brethren of the Kitcat by declaring that it was no great matter whether he saw them or not. "For nine of them," said he, "have such *bad* constitutions that all the physicians in the world can't save them; and the other six have such *good* constitutions that all the physicians in the world can't kill them."

According to Henry Mayhew, of London, there are upwards of 75,000 individuals, or about one-fortieth of the whole population of the metropolis, getting their living in the streets. These are severally:—

Street Sellers,	Street Buyers,
" Finders,	" Performers,
" Artists and Performers,	" Artisans, or
Working Pedlers, and Street Laborers.	

There are upwards of 100 corn-doctors, or *chiropodists*, who manage to eke out a subsistence; and some of them exhibit quite a good deal of eloquence as they pass through their beats—for each one has his customers and particular streets.

The London cat and dog's meat carriers or sellers—nearly all men—number at least 1,000. It is believed by one who has been engaged at the business for 25 years, that there are from 900 to 1,000 horses, averaging 2 cwt. of meat each, boiled down every week; so that the quantity of cats and dogs' meat used throughout London is about 200,000 pounds per week, and this, sold at the rate of 2½d. per lb., gives £2,000 a week for the money spent in cats and dogs' meat, or upwards of £100,000 a year.

There are 14 *General Hospitals* in London, making up 3,526 beds for in-patients; they received, in 1867, 32,199 in-patients, and had 399,146 out-patients.

Sixty-six special institutions, for every conceivable ailment, have furnished accommodation for 13,144 in-patients, and 152,079 out-patients, within the same space of time. Some of these have been in operation 300 years. The oldest among them is *St. Bartholomew's Hospital*, which was founded in 1123, and re-founded in 1547, under Henry VIII. It has 650 beds, and its income is over £30,000 per annum.

Dr. Clement Godson, of London, has prepared the subjoined midwifery statistics—from January 1, 1862, to December 31, 1868:—Of 5,734 deliveries in *St. Bartholomew's Hospital*, there were 49 cases of twins; 1 in 117.02, or 0.855 per cent. Of the 5,783 children born, 3,065 were males, that is, 53 per cent.; 2,718 were females, that is, 47 per cent., so that the excess of males over females was 6 per cent.; 5,502, or 95.95 per cent., were head presentations; 13, or 0.24 per cent., were face presentations; 64, or 1.12 per cent., were breech presentations; 35, or 0.61 per cent., were presentations of some part of the lower extremities; 5,504, or 95.17 per cent., were born living. Twenty-one women, or 0.37 per cent., died either within a month of delivery, or from the effects of labor. The forceps were used 128 times. Craniotomy was performed 4 times, and the mother recovered in every instance.

Guy's Hospital, Southwark, was founded by Thos. Guy, Esq., a bookseller, in 1721, who left the sum of £220,000 as an endowment. It has a yearly income of £27,000, and 575 beds. This is the largest hospital in London. An additional sum of £200,000 was left to it in 1829 by a Mr. Hun.

St. Thomas' Hospital, Southwark, dates as far back as 1553. It has 460 beds, and an income of £31,000. It was removed in 1867, to make way for railway improvements, to the Surrey Gardens, Lambeth, temporarily, awaiting the completion of a new building on the Thames, between Lambeth and Westminster Bridge.

St. George's Hospital, Hyde Park Corner, was founded in 1733. It makes up 350 beds, and has an income of £25,000, derived chiefly from voluntary contributions.

The London Hospital, Whitechapel-road, was founded in 1740; has accommodation for 450, and has contributed to it, yearly, £17,000.

The Middlesex Hospital is situated in Goodge Street; has 385 beds, and was established in 1745. It is supported by contributions.

Bethlehem Hospital, Lambeth, better known as "Bedlam," was built in 1547, for the reception of pauper lunatics. It has an income of £15,000, and accommodates 240 patients.

The model asylum for lunatics is *The County Lunatic Asylum*, at Hanwell; it affords accommodations for over 1,300 patients. Its income from county and parish rates amounts to £40,000.

The subjoined hospitals are supported by private benevolence:—*Westminster Hospital*, near the Abbey; *University College Hospital*, Gower Street; *King's College Hospital*, near Clare Market; *Charing Cross Hospital*, Agar Street.

In short, there are in London and vicinity 200 hospitals, infirmaries, asylums, and almshouses—including 31 dispensaries.

Through the kindness of Mr. Hinton we gained an introduction into King's College Hospital and University College Hospital, and witnessed at our second visit an operation for the removal of the entire *right* clavicle for osteo-sarcoma. The patient was a male, about 40 years of age. The patient, we are informed, made a quick recovery, but the case has not been previously reported. Sir Wm. Fergusson was the operator, and those who have been permitted to witness the manipulations of this great surgeon with the scalpel, can vouch for his noted dexterity and gracefulness in surgical operations.

In one of the late issues of the *Leavenworth Medical Herald*, Dr. F. Cooley, of Kansas City, Mo., has reported an extirpation of the entire *left* clavicle for osteo-sarcoma with perfect success. The patient was a male, aged 30 years, and a native of Kansas City, Mo. Nine days after the operation he walked about the room. Twenty days from the operation he visited Dr. C.'s office, completely recovered.

Every medical man visiting London should view the renowned *Museum of the College of Surgeons*, situated on the south side of Lincoln's Inn Fields. The Government, about 70 years ago, bought John Hunter's anatomical museum and presented it to the College. The contents of the museum are illustrative of the structure and functions in the healthy and diseased states, and have been classified and arranged with great skill by Prof. Owen.

Two Cases of Shoddy Disease—an affection not much known in America, as *shoddy*, from old clothes, is not so extensively manufactured in this country—were pointed out by Mr. Beardsley, connected with Dr. Baker Brown's late *Surgical Home*. These patients came from the little town of Dewsbury, which is the metropolis of the manufacture of shoddy. The disease popularly known as "shoddy fever," which is of frequent occurrence in Dewsbury, is a species of bronchitis, caused by the irritating effect of the floating particles of dust upon the mucous membrane of the trachea and its ramifications. In general the attack is easily cured—particularly if the patient has not been for any length of time exposed to the exciting cause—by effervescing saline draughts to allay the symptomatic febrile action, followed by expectorants to relieve the mucous membrane of the irritating dust; but a long continuance of employment in the contaminated atmosphere, bringing on as it does repeated attacks of the disease, is too apt in the end to undermine the constitution and produce a train of pectoral diseases, often closing with *pulmonary tuberculosis*. Ophthalmic attacks are by no means uncommon among the shoddy-grinders, some of whom, however, wear wire-gauze spectacles to protect the eyes. As regards the effect of the occupation upon health, it may shorten life by about five years on a rough average.

"Shoddy fever" is, in fact, a modification of the very fatal disease induced by what is called "dry grinding" at Sheffield; but of course the particles of woollen filament are less fatal in their influence than the floating steel-dust produced by the operation in question.

While alluding to Dr. Baker Brown, we learn that this surgeon is again restored to health, and has recently added to his already brilliant operations by successfully removing a large fibroid tumor of the abdomen from a patient who is reported to be in excellent health.

Specialties succeed in London if not pushed too far. Mr. T. Spencer Wells makes £10,000 and upwards yearly by his ovariotomy and other female business. General operative surgery is one branch, consulting lunacy practice is another, and midwifery is another. One London surgeon receives his £70 per week by hemorrhoids alone.

There are now in the United Kingdom twenty institutions which exercise the power of conferring medical degrees, or of granting licenses to practise medicine or

surgery. They are as follows, with the number of their respective graduates or licentiates during the ten years ending with 1867 attached to each:—

University of Oxford	17
University of Cambridge	61
University of Durham	5
University of London	241
University of Edinburgh	524
University of St. Andrew's	497
University of Glasgow	359
University and King's College, Aberdeen	263
Marischal College and University of Aberdeen	161
University of Dublin	143
Queen's University, Ireland	34
London College of Physicians	242
Edinburgh College of Physicians	68
Dublin College of Physicians	97
London College of Surgeons	4,915
Edinburgh College of Surgeons	1,066
Glasgow Faculty of Physicians and Surgeons	367
Dublin College of Surgeons	582
London Apothecaries' Company	2,823
Dublin Apothecaries' Company	214
Total	12,679

To show what it costs in the United Kingdom to become a general practitioner, the subjoined figures are noted:—

Cost of professional instruction	£100	0	0
Cost of diploma of London College of Surgeons	23	2	0
Cost of diploma of London Apothecaries' Company	10	10	0
Apprenticeship premium	150	0	0
Clothes and miscellanea for five years.	125	0	0
Board and lodging for three years	225	0	0
Total	£663	12	0

Six hundred and fifty pounds is a fair approximation to the amount usually spent by the better class of frugal and industrious young men in qualifying themselves as "general practitioners," by the method enjoined upon them by the College of Surgeons and the Society of Apothecaries, in the exercise of the authority given them by the State.

Before concluding this paper we will remark that the immense number of street-beggars and prostitutes of London, Liverpool, and other large towns of Great Britain, which are seen on every hand the moment one touches foreign shores, help the tourist from the New World to form a wrong idea of the morality and intelligence of our British friends. As civilization advances in America, undoubtedly within fifty years the same characters will be reproduced in New York, Boston, and other noted seaports of the New World, and in equal numbers.

The number of regular prostitutes in the British Isles is estimated at 46,000, and those of a superior class at 322,000. The assumed number of prostitutes in London, of all classes, is about 80,000. It is computed by Dr. Ryan that £8,000,000 are expended annually on this vice in London alone. The average earning of each prostitute is £100 per annum. It is probable that, exceptions apart, the whole of the British prostitute population is renewed every seven years.

Of the "regular prostitutes" it is believed that very few escape contagion at one part or other of their career, while of the occasional and superior classes of prostitutes, of whom less is positively known, it cannot be questioned that very many, perhaps the majority, become infected. If we add to the number of women the number of men who yearly contract venereal disease, a frightful picture of the organic poisoning which is going on there is presented to our minds.

Probably the picture could be drawn in many parts of our own country which would nearly equal in hideousness St. Giles', Petticoat Lane, Ratcliffe Highway, and New Cut, Lambeth, in London.

At three metropolitan hospitals, viz., St. Bartholomew's, Guy's, and the Royal Free, the cases of venereal disease actually treated reach to the yearly number of 73,700; while at King's College, University College, St. Mary's, Westminster, London, and Middlesex Hospitals, sufferers from one form or other of venereal disease amount to from twenty to thirty-three per cent. of the out-patients daily seen. The above figures are sufficient to warn us of the enormous extent of the mischief in question.

An intelligent and renowned medical writer states in the *Westminster Review* that "in England, at all events, the human constitution is deteriorating; that it is more prone to disease than it was thirty years ago; and that within the same period the average duration of life has lessened. According to the returns of the Registrar-General, almost all diseases notable for their fatality are, in proportion to the number of persons living, much more fatal than they were formerly."

The death-rate advanced in the proportion of about 1 in a 1000 to the population of England and Wales in the twenty-nine years between 1838 and 1866, inclusive; and the speed at which it advanced in the more recent portions of that period may be judged from the following average percentage of deaths:—From 1838 to 1863 it was 2·242 per cent.; from 1860 to 1866 it was 2·261 per cent.; from 1863 to 1866 it was 2·348 per cent. This corresponds to 3,000 additional deaths in London alone, and to about 22,000 in the whole of England and Wales.

This slight sketch of the extent of prostitution and venereal disease in the British Isles gives us some idea of the "social evil" there—this great and disgusting blot on civilization.

Who can tell the pestiferous influence exercised on society by one single fallen woman? Woman, waylaid, tempted, deceived, becomes in turn the terrible avenger of her sex. One and another who has been educated in an atmosphere redolent of virtue and principle, and has given promise of high and noble qualities, falls a victim to the prevalence of meretricious allurements, and carries back to his hitherto untainted home the noxious influence he has imbibed. Another and another, within the range of that influence, is made to suffer for his sacrifice of moral rectitude, and they, in their turn, become the agents and originators of fresh evils.

No. 105 East Twenty-sixth Street, New York.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 13, 1870.

Dr. J. C. Hutchison, President, in the Chair.

The Committee on Microscopy reported the specimen of uterus presented at the last meeting, by Dr. C. C. Lee, to be one of myoma.

HEART DISEASE AS A CAUSE OF DEATH.

Dr. Finnell exhibited, on behalf of Dr. W. Beach, a portion of the aorta removed from a man ætat. 40, who died suddenly. Extensive calcification of the aortic

valves was the evident cause of death. The ascending arch was also the seat of the most abundant deposit that he had ever seen. The specimen furnished the occasion for the remark, that all forms of organic disease of the heart are liable, from slight causes, to result in sudden death, the statements at the recent meetings of the County Society "to the contrary notwithstanding."

FORCED ABORTION AND DEATH.

A second specimen consisted of the uterus and appendages taken from the body of an unmarried woman, who died as the result of forced abortion. He was indebted to Dr. O'Callahan, of Jersey City, for the specimen. The victim was four months advanced in pregnancy, and, determining to rid herself of the fœtus, consulted a noted abortionist, who, according to her statement, introduced silver tubes several times. At the end of a week abortion took place, followed by violent peritonitis, which terminated in death on the sixth day. At the autopsy purulent deposit was discovered in the pelvis, with adhesions at all points. The cavity of the cervix uteri was furrowed with lacerations, evidently done with some smooth instrument, such for instance as a catheter. In connection with this case he referred to another similar one, in which, at the same period of utero-gestation, abortion was produced by some patent pills. The patient applied to an advertiser, and received instructions to take five, instead of which she took nineteen. The result was extreme hypercatharsis, metritis, and speedy death. As is quite usual in such cases, the poor victim refused to disclose the name of the murderer.

DEPRESSED FRACTURE OF SKULL IN A DROWNED MAN.

A third specimen exhibited by Dr. Finnell was a portion of calvarium removed from a body that had been in the water for many days. Decomposition was so far advanced that no absolute cause for death was discoverable, save perhaps that which was to be seen in the portion of skull presented in the shape of a fracture extending from the middle of the frontal bone obliquely outwards, crossing the fronto-parietal suture, and terminating two inches to the left of the parietal bone. The fracture was markedly depressed, was four inches in length and a quarter of an inch in width, and seemed to have been produced by some such instrument as an axe. The corresponding portion of the vitreous table was also fractured, and depressed to the extent of an inch in length to half an inch in width. The question was,—Did this man receive this injury at the hands of an assassin, or was it inflicted by falling against some projecting rock in the water? The presumption seemed to be in favor of the former.

Dr. Sayre remarked that the specimen illustrated the necessity of trephining in cases of comparatively slight external evidences of depression of bone.

EPITHELIAL CANCER OF LIP IN A PATIENT AGED THIRTY-TWO.

Dr. C. C. Lee presented an epithelial cancer of the right lower lip, which he had removed that afternoon. The specimen was interesting only in reference to the age of the patient—the subject, a male, being only thirty-two years old. The growth began eight weeks ago as a small pimple, which subsequently ulcerated and enlarged. He was not a smoker, neither were there any carious teeth in the neighborhood. The mother and grandfather had died of cancerous disease. The growth in the lip presented all the typical appearances of epithelial cancer in its earlier stages. It was removed by the ordinary V-shaped incision. Referred, by request, to Committee on Microscopy.

Dr. Finnell remarked that he had met with two cases of epithelial cancer of lower lip in patients under forty-five years of age, being respectively forty and forty-two.

Dr. Rogers had treated a young German for the same disease, in the same locality, who was under thirty-five.

INTUSSUSCEPTION IN THE ILEUM AND SIGMOID FLEXURE OF THE COLON.

Dr. Lewis Smith presented two specimens, one of which was a large intestine removed from an infant that died at the age of five months, of hemorrhage from a thoracic abscess. At the autopsy there were found several simple intussusceptions in the ileum, and one in the sigmoid flexure of the colon. He did not recollect ever to have met with the lesion in that locality unattended with symptoms. For the purpose of explaining the frequency of the occurrence of that accident in that particular locality, he called the attention of the members to the loose attachments of the meso-colon, which allowed from a quarter to a third of the gut to descend below the brim of the pelvis. The involution, although perfect, did not produce perfect closure of the tube.

SACCULATED KIDNEY FROM CALCULUS.

A second specimen was a left kidney removed from a female aged sixty-four, who died in the Charity Hospital so suddenly that no satisfactory history had been obtainable. On making the post-mortem examination gall-stones about as large as peas were discovered in the gall-bladder. The lesion of chief interest, however, was found in the organ exhibited. The right kidney was somewhat larger than natural, and appeared to have undergone slight fatty degeneration. The left kidney was atrophied and sacculated; the pyramidal portion was nearly destroyed, and the cortical substance somewhat compressed. In searching for the cause of this condition a calculus was discovered in the upper portion of the ureter. The obstruction to the tube was not, however, complete. No opportunity had been offered, up to the time of presentation, for a chemical analysis.

A NEW METHOD OF PUNCTURING THE BLADDER.

Dr. Buck presented a specimen of bladder and rectum taken from the body of a patient of Saint Luke's Hospital, aged 37. The case was one of old stricture, with numerous fistulous tracts running in different directions and opening in the scrotum, perineum, and on the inside of both thighs; on the whole, the most aggravated case of the sort that the presenter had ever seen. In 1851 the patient contracted gonorrhœa, which from his account was quite a severe attack, and for which he was under treatment a long period. He finally was able to resume his seafaring life, when he had a fistula in ano for which he underwent an operation in one of the London hospitals. Subsequent to this an opening formed in the perineum from which urine escaped. He gave no account of any aggravated symptoms such as might accompany an old and bad stricture. When admitted to Saint Luke's Hospital urine was escaping from no less than fourteen fistulous orifices. A stricture was then found at the bulbous portion, and was operated on by an external incision. This had failed to close at the time Dr. Buck took charge of the patient. The urethra was exposed for at least an inch at its perineo-scrotal portion, and a number 12 sound could be passed into the bladder through the entire length of the urethra. The bladder itself was not in as bad a condition as might have been supposed; it could retain

its contents for three or four hours at a time, and there was no considerable deposit of muco-pus. His general condition was fair. In this case there seemed to be no resource left to the patient save that of cutting off the flow of urine through these fistulous openings, and thus allowing them to close up. The expedient was proposed to the patient, who was only too ready to accept anything that promised relief. The operation was accordingly performed on the Wednesday preceding the meeting. The perineum presented an appearance not easy of description, being generally thickened throughout and covered with ridges and pouting eminences, some the size of the end of the thumb, which marked the situations of the numerous fistulæ. Three or four of these redundancies were snipped off. A fistulous opening was also found to communicate with the rectum about two inches from the anus, which allowed the passage of flatus not only through it, but through other openings with which it in its turn communicated.

The patient, after being etherized, was placed in the usual position for lithotomy. A full-sized sound was introduced to serve as a guide, and an incision was made, such as would be required in the bilateral operation for lithotomy. The operator followed up the tract by the aid of the thumb in the wound and finger in the rectum, and, gradually working his way back, encountered the fistulous opening, which communicated with the gut. A tract was then worked to the distant margin of the prostate. The parts were not so readily identified, owing to the thickening; still, the operator was able to satisfy himself of his position, and the canula of the bladder trocar was first introduced upon his finger to the place where the bladder was to be punctured. The trocar was then passed, its handle depressed, and the puncture into the bladder made, encountering the sound. This canula was left in the bladder, and an inner canula afterwards introduced with rounded end and lateral openings, so as to protect the bladder from the edges of the first tube.

Twenty-four hours after the operation the patient was found in a comfortable condition, his water escaping exclusively through the canula, and controlled by a plug. No complication showed itself until forty-eight hours after the operation, when he had a rigor and began to complain of pain in the lower part of the abdomen, more particularly in the left iliac region. The abdomen soon became tumid, and the characteristic vomiting of peritonitis soon showed itself. The urine continued to be discharged freely through the instrument.

The treatment employed was narcotic, by hypodermic injections of morphine and local soothing applications. He survived until Monday morning. Late on Sunday evening, Dr. B. noticed that there was an emphysematous crepitation in the right iliac region and towards the pubes.

Dr. Buck stated that his fear was, that he had damaged the peritoneum in his operation, notwithstanding he felt very certain of his geography.

At the autopsy the incision, as it approached the pubes, opened into an interparietal abscess that extended towards the left iliac region, but was separated from the abdominal cavity by the peritoneum and probably the transverse fascia. The crepitus felt during life was no doubt caused by the gas generated in this abscess. The intestines occupying the pelvis were adherent to each other and to the parietes by loose lymph, which floated in a moderate amount of seropurulent matter. The cul-de-sac between the bladder and rectum showed no more appearance of peritoneal inflammation than elsewhere. The tract of the puncture was separated by at least half an inch of tissue from the peritoneal cavity.

The question had suggested itself to Dr. B. since the autopsy, whether this peritonitis had not been dependent on the breaking of the abscess into the peritoneal cavity, this abscess having probably been primarily caused by urinary infiltration of old date. It was to be regretted that no search had been instituted with the view of determining if such a communication had existed. An interval of forty-eight hours having elapsed before the peritoneal symptoms showed themselves, might perhaps be regarded as corroborative evidence that the operation itself was not chargeable with the peritonitis. The close proximity of the abscess to the peritoneum might of itself have caused the peritonitis.

The inner surface of the rectum was as black as ink, as far as it was exposed. The inner surface of the bladder was thickened, contracted, and a good deal reddened by congestion.

The operation was not a usual method of puncturing the bladder, and in some cases he believed it had advantages over others. In conclusion, he stated his determination of resorting to it for the purpose of relieving the bladder in obstinate and violent cystitis.

Dr. Sayre remarked that Dr. Parker had proposed some years ago a similar plan for relieving the bladder.

Dr. Sands believed that Dr. Parker's method (vide Trans. Med. Soc., State of New York, 1867, page 345) had all the advantages of that proposed by Dr. Buck, without its special dangers. To be sure, in the present case, there seemed to be a doubt whether the abscess in the pelvis existed previous to the operation. It appeared, however, quite probable that the inflammation of the pelvic areolar tissue, if not set up by the procedure, was at least aggravated. Again: If further experience of this mode showed it a safe one, it would entirely unsettle the notions of surgeons and anatomists in regard to the danger of invading that part of the body with the knife. It was a maxim in almost all operations in this region to restrict the incision to the prostate, and not permit it to pass through the fibrous tissue which invests the organs, else all the consequences of urinary infiltration in the recto-vesical space may ensue. He thought it remained to be shown whether the operation was not a very dangerous one, and he failed to see its advantages over the simpler method by Dr. Parker. By the latter, the indications for relieving the bladder were equally well met by cutting behind the point of stricture.

Dr. Buck, in the latter connection, remarked, that an incision through the membranous portion of the urethra would have involved the diseased parts.

Dr. Rogers remarked that he had under observation a case as similar to Dr. Buck's as any one case could be, in which a perineal incision had been made anterior to the prostate. All the urine for the past three months had been made through that opening. The irritability of the bladder had in consequence entirely disappeared, and the extensive and numerous fistulous tracts down the thighs had entirely healed. Besides the grand stricture there were other minor ones, which had been overcome by the process of dilatation.

SPONTANEOUS DISCHARGE OF HEAD OF FEMUR.

Dr. Nolan exhibited the head of a femur, that had been discharged spontaneously from a boy aged fifteen years. The patient had been attacked with acute inflammation of one of the hip joints, which in the course of time developed all the characteristic symptoms of morbus coxarius. The usual local antiphlogistic mea-

sures had been resorted to without marked relief, when finally confinement and the splint was recommended. To this latter the patient refused to submit. An abscess formed on the outer aspect of the thigh, just below the trochanter major, opened, and kept discharging until finally the portion of the bone referred to was expelled. At the time of the report the patient was doing well. The limb was an inch and a half shorter than its fellow, the toe pointing outwards. The specimen presented the appearance of an epiphyseal separation.

The Society then went into executive session.

Correspondence.

A NEW LACHRYMAL STYLE.

To the Editor of the Medical Record.

Sir—In the Transactions of the American Ophthalmological Society for 1869 I notice an article by Dr. John Greene, of St. Louis, Mo., on the use of leaden styles in obstructions of the lachrymal passages. For the past four years I have been in the habit of using styles made of pure silver wire—the same that is ordinarily used for sutures. The manner of making them is this: Take a piece of the wire of the proper gauge, and having ascertained the precise length needed, measure the distance on the wire, and then double it two, three, or more times, as may be necessary to produce the requisite thickness; taking care to make one of the loops or folds at the end about two lines longer than the rest, to form the head or support when the instrument is in position. The two ends are then to be seized firmly with forceps and the wires twisted into a miniature rope, the free ends clipped off and smoothly bent down, the loop for the head expanded and turned at a proper angle, and the style is complete.

The advantages of this style are that it can always be made available, the resources of every surgeon's pocket-case affording the necessary materials for making them extemporaneously. The twist of the wires favors the flow of the tears along its sides, and affords convenient lodgment for any medicines in the form of ointments or cerates which it may be necessary to apply to the walls of the canal. Their flexibility is sufficient to allow of their adaptation to any curvature of the passages, without the disadvantage of too great flexibility, as is the case with the smaller sizes made from lead, and which thereby renders their use impossible without a special instrument for introducing them. Their length and thickness can be accurately adjusted to the wants of every case, without the necessity of either keeping a large assortment constantly on hand, or of procuring them from the instrument-maker, by which much trouble is often incurred, and much valuable time lost in the treatment of a case. It must be borne in mind that only pure silver wire is fit to be used in making them, galvanized iron or other material being unsuitable.

Chas. Bliss, M.D.

861 West 43d Street.

Ovariotomy during Pregnancy.—Last September, Mr. Spencer Wells performed ovariotomy in the fourth month of pregnancy. There had been rupture of the cyst and peritonitis. The woman recovered, and has since been delivered of a child at full term.

Premature Puberty.—A case of premature puberty is mentioned in the Journal of the Gynæcological Society of Boston, where a child began to menstruate at the age of three-and-a-half years.

Medical Items and News.

Delegates to the American Medical Association.—The County Society has appointed the following gentlemen delegates to the approaching meeting of the American Medical Association: Drs. S. A. Raborg, E. C. Harwood, Wm. T. Lusk, E. H. M. Sell, J. L. Little, J. C. Smith, W. R. Whitehead, T. C. Finnell, Robert Newman, George M. Beard, Chas. A. Leale, Moreau Morris, J. C. Nott, H. G. Piffard, B. S. Thompson, John P. Garrish, A. E. M. Purdy, and Geo. T. Elliot. Any of the above unable to attend, and any others who may wish to attend as delegates, are requested to communicate with Dr. A. E. M. Purdy, Secretary, 260 Madison Avenue.

The following gentlemen have been elected from the New York Pathological Society:—Dr. E. Peugnet, H. Knapp, W. B. Bibbins, W. Neftel, T. C. Peters, E. G. Janeway, E. H. M. Sell, E. Eliot, R. Watts, E. Lee Jones, C. C. Lee, J. A. Monell, A. Flint, A. Clark, W. H. Carmalt.

Albany Medical College.—Dr. Thomas C. Durant, of New York, a graduate of the College, and an early student of Drs. March and Armsby, has given $15,000 to endow the "March Professorship." Drs. E. R. Peaslee and Meredith Clymer, of New York, and Dr. William P. Seymour, of Troy, have accepted invitations to deliver short courses on special subjects the coming fall.

New York State Hospital for Diseases of the Nervous System.—A meeting of the trustees of this recently incorporated charity was held at the residence of William H. Appleton, Esq., No. 3 Madison avenue, on the evening of the 23d inst. The following is a list of the trustees: William H. Appleton, George T. Elliot, Edward Cooper, L. A. Sayre, H. C. Fahnestock, Thurlow Weed, William A. Hammond, Roswell D. Hatch, William H. Van Buren, F. S Winston, James R. Wood, and Austin Flint. The organization of the Board was completed by the election of the following officers: President, William H. Appleton; Vice-President, Thurlow Weed; Treasurer, H. C. Fahnestock; Secretary, R. D. Hatch. The medical officers are as follows: Physician-in-chief, Dr. William A. Hammond; Consulting Physicians, Drs. Austin Flint and George T. Elliot; Consulting Surgeons, Drs. James R. Wood and Lewis A. Sayre. The trustees are confident of being able to erect a suitable building shortly. For the present they will rent one.

Dr. Jonathan Letterman Injured.—This surgeon, formerly in the United States Army, now Coroner of the city and county of San Francisco, met with a fracture of the femur, above the knee, February 21st, by being thrown upon the pavement while stepping from a carriage.—*Cal. Med. Gazette.*

Alexis St. Martin.—This individual, whose case has furnished such rare opportunities for observing the functions of digestion, is still alive and well. He lives in Cavendish, Vt.

Death from Chlorine Gas.—A case of death occurred lately in Dublin from the inhalation of chlorine gas. On post-mortem examination the chlorine was detected in the ventricles of the brain, and less perceptibly in the bronchial tubes. This is, we believe, the first case of death that has ever taken place from this gas.—*Lancet.*

Liebig.—Professor Liebig has received the Albert Medal from the Society of Arts, Trade, and Manufac-

ture of Great Britain. This is considered to be a great distinction, as only one such medal is awarded annually; and this is the first that has been given to a German.

PATHOLOGY OF INSANITY.—Dr. Tuke, in thirty cases of insanity, has noticed in all microscopic changes in the brain tissue.

TEA CULTURE IN TENNESSEE.—The tea plant is in successful cultivation some ten miles from Knoxville, Tennessee, where it has been raised for the past ten years. The Agricultural Department at Washington furnished the original plants in 1858. The plant is hardy, and needs no protection from frosts. Good judges pronounce it to be not inferior in fragrance and flavor to the imported Young Hyson.—*Nashville Jour. Medicine and Surgery.*

ANÆSTHETICS.—The medical men of Lyons, France, have declared for ether, and against chloroform. M. Petrequin, ex-Surgeon-in-Chief of the Hôtel Dieu at Lyons, says:—"It is evident that the danger lies in chloroform itself. If it kills, it is not because it is impure; *it is because it is in its nature a poison.*"

PATIENTS TREATED IN BELLEVUE HOSPITAL.—The whole number of patients treated in this institution during the year 1868 was 7,085. The number discharged cured or relieved was 5,597. The number of deaths was 795.

THE SOCIAL EVIL IN PHILADELPHIA.—According to the recent investigations of the Midnight Mission, there are in Philadelphia the large number of twelve thousand professional prostitutes, not including the irregulars.

ETHER DRUNKENNESS IN IRELAND.—In the *Medical Press and Circular* we find a communication from a Dr. Draper, stating that ether is now extensively used as an intoxicating beverage in the north of Ireland. He says:—"So far as I can learn, the introduction of the practice dates from about five years since, and it is curious in its very origin. While it is only right to say that one of my correspondents attributes it to the habit acquired by the medicinal use of the drug in cases where alcoholic stimulants were contra-indicated, and another to the desire of 'getting drunk more cheaply,' I have not found either of these theories to bear examination, and my authorities are, with these two exceptions, unanimous in the opinion that ether drinking is a consequence of the laudable efforts made by the Roman Catholic clergy in inducing their flocks to abstain from whiskey. The usual quantity of ether taken at one time is from two to four drachms, and this dose is repeated twice, thrice, or even four and six times daily. It is taken unmixed with water; indeed, its very slight solubility in that fluid would make this a useless precaution; but the usual practice is to take, first, a mouthful of water, then the dose of ether, and again a mouthful of water."

SWALLOWING OF INDIGESTIBLE SUBSTANCES.—Sir William Fergusson calls attention to the case of a sailor, aged 23, who was in Guy's Hospital in 1853, and who, in the course of ten years, swallowed, at different times, at least thirty-five knives. Some of these, or eroded portions, were occasionally vomited or passed per anum. He finally died from exhaustion, and, on opening his body, forty different pieces of blades and handles were found in the abdomen.

DR. GROUX, whom the profession will remember since his advent in this country, in 1858, with a complete absence of the sternum—which was congenital—has settled in Williamsburgh, N. Y.

A SIMPLE AND USEFUL OPHTHALMOSCOPE.—Dr. Wecker (*Boston Medical and Surgical Journal*), at the annual meeting of the Heidelberg Ophthalmological Society, exhibited a simple fixed ophthalmoscope, by means of which two persons could examine a patient at the same time, the image being caught on a transparent sheet of glass.

THE PHOSPHURET OF ZINC.—Meredith Clymer, M.D. (*N. Y. Med. Journal*), states that the internal action of the salt, according to the experiments of Dr. Gubler, varies according to the amount of pepsin present. In those persons where there is but little gastric juice secreted, to small eaters the drug cannot be given without giving rise to gastric troubles and to diarrhœa; while it may be supported by large eaters. Dr. Gubler, who is a high authority, says that phosphorus seems only to be absorbed under the form of phosphuretted hydrogen gas, Ph. H_3; and that we should allow such preparations as will give rise to it, or to free phosphorus itself. All others are inert.

Dr. C. believes, from no inconsiderable experience with it, that phosphoric acid and its salts often do much good in many disorders of the nervous system, and as a eutrophic generally.

REDUCTION OF FARE FOR DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.—The Permanent Secretary, William B. Atkinson, M.D., of Philadelphia, under date of April 19, 1870, writes:—The following commutation has *thus far* been obtained:—

Morgan Line of Steamers (N. O.) will pass delegates for *one fare* the round trip.

The Charleston and Savannah, Atlantic and Water Line, *via* Knoxville or Nashville and Louisville; Orange and Alexandria; South Carolina; North-Eastern; Short Line between Louisville and Cincinnati Railroads, will *return free* on certificate of Permanent Secretary.

Excursion tickets will be issued by the Baltimore and Ohio; Milwaukee and St. Paul; Milwaukee to Chicago; Louisville and Cincinnati; Louisville and Nashville; Mobile and Ohio; Mobile and Montgomery; Memphis and Louisville; N. O., J. and G. N.; Hannibal and St. Joseph; Tennessee and Virginia; Mississippi Central; Memphis and Charleston, *all at one fare;* New Jersey Transportation Line, from New York to Washington and back, $10.70; New York and Washington Air Line, one-third less; Steamers and Mobile Trade Co at one fare; Boston to New York, $7; Philadelphia, Washington and Baltimore, to Washington, $6.50; Louisville and Cincinnati steamers, $5, with meals and rooms.

The delegates from New Orleans will leave at 5 P.M. by special sleeping car on Thursday, April 28, *via* N. O., J. & G. N.; Mississippi Central, Memphis and Charleston, and Tennessee and Virginia Railroad, arriving at Washington on Sunday. The party to consist of not less than twenty-five, including families of delegates, and return by same route. Fare, $55; ticket good to New York for thirty days.

A second party of not less than twenty-five may travel *via* Chicago, the Lakes, New York, and Philadelphia, upon the same terms as above.

SUCCESSFUL CASE OF TRANSFUSION.—Much interest has been excited in professional as well as general circles by a case of uterine hemorrhage, in which transfusion was successfully performed by Drs. Beatty, Colles, and McDonnell. About ten ounces of blood were taken from the husband of the lady.—*British Med. Journal.*

American Medical Association.

TWENTY-FIRST ANNUAL MEETING,

HELD IN LINCOLN HALL, WASHINGTON, D. C.

FIRST DAY—MAY 3, 1870.

PROF. G. MENDENHALL, PRESIDENT, in the Chair.

THE Association met pursuant to adjournment, and was called to order by the President, at 11 o'clock A.M.

Prayer was offered by Rev. Charles B. Boynton, D.D., of Washington, D. C.

ADDRESS OF WELCOME.

DR. THOMAS ANTISELL, of Washington, D. C., in a brief and appropriate address, bade the members of the Association a cordial welcome. The Association was peculiar in representing an immense area of territory, and in bringing together medical men familiar with the extremes of disease incident to widely separated regions of the country. He trusted that out of such reunions might grow increased good-fellowship and *esprit de corps*, increased respect from the public toward the profession, higher modes of thought, purer springs of action, increased peace within the profession, and increased strength without. He bade one and all a hearty welcome to the metropolis.

ENTERTAINMENTS AND RECEPTIONS.

The following was announced as the programme for the evenings at the disposal of the Association:—

Tuesday, May 3d.—Reception of the Association by the President of the United States, at 8 P.M.

Wednesday, May 4th.—At 7 P.M., visit of the Association to the Army Medical Museum, and reading of papers.

Thursday, May 5th.—At 8 P.M., illumination of the Capitol dome, and at 9 P.M., reception by Mayor Bowen, of Washington.

CREDENTIALS.

The Report of the Committee on Credentials was presented by Dr. Thomas Antisell, D. C., in which it was stated that they excluded the delegates from the National Medical Society, the American Academy of Medicine, the Howard University Medical College, and the Alumni Association of the Medical Department of Georgetown College.

The minority report of the same committee was read by Dr. Robert Reyburn, protesting against the action of the committee. Dr. Reyburn attempted a personal explanation, and was proceeding with rather violent charges and criminations, when Dr. N. S. Davis, of Chicago, moved that the report be referred to the Committee on Ethics, without remark. A sharp debate ensued, and the motion was finally carried.

DR. BUSEY submitted a protest against the admission of Dr. C. C. Cox, from the State of Maryland, and Dr. Cox took the stand to reply, but Dr. Davis insisted that this matter and all similar grievances be referred to the Committee on Ethics.

ETHICS.

DR. SAYRE, of New York, rose to request that the serious charges made against his character by Dr. Rupanner be referred to a Special Committee on Ethics, as he was chairman of the regular committee, and could not consistently act in the premises.

DR. N. S. DAVIS moved that a Special Committee on Ethics be appointed for that purpose. Carried.

The President then appointed Dr. Alfred Stillé, Dr. N. S. Davis, Dr. J. M. Keller, Dr. H. F. Askew, and Dr. Woodward, U. S. A., a Special Committee on Ethics to consider the above case.

ADDRESS OF THE PRESIDENT.

After expressing his high appreciation of the honor conferred on him by the Association, the President proceeded to review briefly the history and work of the Association during the twenty-three years that it had been in existence. That work had been so vast that merely an outline of it could be given in a single address, but it could be safely asserted that progress had been at least as great in medicine as in any other department of science. The co-operation of the entire body of active practitioners had accomplished important results, and those who questioned the fact were those who had themselves done nothing to advance the cause. When they had done their best it would be time for them to complain of the work of the Association.

The influence of the Association had effected a great reform in the matter of medical education, had raised the standard of attainments, and had drawn the line distinctly between the honorable practitioner and the charlatan. We had now a Code of Ethics which in itself was one very important result of the labors of the Association. The Code of Ethics should be made familiar to every student of medicine, and impressed upon all students by their teachers.

Another great work of the Association was the influence exerted on American medical literature, which had advanced to such an extent that we could now return all obligations to our transatlantic brethren. The literature of the Association was very considerable, and he would suggest that much of it was well worthy of publication, but was now lying idle in the archives of the society. There was no time even to read many of the valuable original papers received; and in this connection he would suggest that a longer time than was usual might very profitably be spent by the Association at its annual meetings.

In regard to medical education, the time had arrived for decisive action. Advance was practicable and should be insisted upon, and the schools held accountable for the execution of whatever plan might be deemed best. Of course all could not be done at once, but some system should be matured and adopted without further delay. That there was abundant room for improvement, there could be no manner of doubt.

The custom of the Association had been to send delegates to foreign medical societies. That courtesy had not been reciprocated, and he would recommend that hereafter no delegates be sent to societies that have failed to respond to them in the past.

The President then dwelt at some length on the question of copyrights and patent-rights, taking the ground that there was no analogy between them, and that patent-rights ought not to be claimed by the profession either for instruments, surgical appliances, medicines, or modes of cure of any kind.

The President closed his address, after warning the profession against a possible moral evil resulting from the too liberal prescription of the various forms of alcohol and opium, with a touching allusion to the many distinguished medical men who had been removed by death since the last annual meeting.

A vote of thanks was tendered the President for his address, and a copy requested for publication.

REPORTS OF SPECIAL COMMITTEES.

The Secretary, Dr. W. B. Atkinson, announced the following reports of committees:

"On Cultivation of the Cinchona Tree," Dr. L. J. Deal, Pa., Chairman. Reported, and referred to Section on Practical Medicine.

"On the Cryptogamic Origin of Disease, with Special Reference to Recent Microscopic Investigations on that Subject," Dr. Edward Curtis, U.S.A., Chairman. No report. Committee discharged.

"On the Doctrine of Force, Physical and Vital," Dr. John Waters, Mo., Chairman. Not ready.

"On Variola," Dr. Joseph Jones, La., Chairman. No report.

"On the Relative Advantages of Syme's and Pirigoff's Mode of Amputation at the Ankle," Dr. G. A. Otis, U.S.A., Chairman. Reported, and referred to Section on Surgery.

"On a National Medical School," Dr. F. G. Smith, Pa., Chairman. Reported progress. Continued.

"On Commissioners to Aid in Trials involving Scientific Testimony," Dr. J. Ordronaux, New York, Chairman. No report. Committee discharged.

"On the Climatology and Epidemics of Maine," Dr. J. C. Weston. No report.

New Hampshire, Dr. P. A. Stackpole. No report.

Vermont, Dr. H. Janes. No report.

Massachusetts, Dr. H. I. Bowditch. Reported, and referred to Section on Climatology.

Rhode Island, Dr. C. W. Parsons. No report.

Connecticut, Dr. E. K. Hunt. Reported, and referred to Section on Climatology.

New York, Dr. W. F. Thoms. No report. Continued.

New Jersey, Dr. E. M. Hunt. No report.

Pennsylvania, Dr. D. F. Condie. Reported, and referred to Committee on Climatology.

Maryland, Dr. O. S. Mahon. No report.

Georgia, Dr. J. Harris. No report.

Missouri, Dr. G. Engleman. No report.

Alabama, Dr. R. F. Michel. Not ready.

Texas, Dr. T. J. Heard. No report.

Illinois, Dr. R. C. Hamil. No report.

Indiana, Dr. J. F. Hibberd. No report.

District of Columbia, Dr. T. Antisell. No report.

Iowa, Dr. J. C. Hughes. No report.

Michigan, Dr. A. Sager. No report.

Ohio, Dr. T. L. Neal. No report.

California, Dr. F. W. Hatch. No report.

Tennessee, Dr. B. W. Avent. No report.

West Virginia, Dr. E. A. Hildreth. No report.

Minnesota, Dr. S. Willey. No report.

Virginia, Dr. W. O. Owen. No report.

Delaware, Dr. L. B. Bush. Continued.

Arkansas, Dr. G. W. Laurence. No report.

Mississippi, Dr. W. Compton. No report.

Louisiana, Dr. L. T. Pimm. No report.

Wisconsin, Dr. J. K. Bartlett. No report.

Kentucky, Dr. J. D. Jackson. No report.

"On Veterinary Colleges, Dr. T. Antisell," D. C. Reported. Dr. Antisell began reading a highly interesting report on this subject, but was interrupted by a motion to refer the paper to the Committee on Publication. Carried.

WORK FOR THE SECTIONS.

The following papers were referred to sections:

"Extraction of Tumor from Knee-Joint," A. B. Stewart, Section on Surgery.

"Intra-uterine Injections," J. Byrne, N. Y., Section on Obstetrics.

"Best Method of Curing the Insane," C. A. Lee, Section on Psychology.

"Veterinary Colleges," Dr. T. Antisell D. C., Section on Materia Medica.

"Cellular Structure of Red Blood-Corpuscle," J. G. Richardson, Phila., Section on Physiology.

"Improved Medicinal Treatment," J. H. Griscom, N. Y., Section on Practical Medicine.

"Median Lithotomy," Jas. L. Little, N. Y., Section on Surgery.

"Imperforate Anus, New Operation for," T. M. Healey, Section on Surgery.

"New Method of Effecting Reductions at the Shoulder-Joint," S. Logan, N. O., Section on Surgery.

"Case of Congenital Occlusion of Rima Glottidis," L. Elsberg, N. Y., Section on Surgery.

"Tubercular Degeneration of Kidney," C. H. Olio, Section on Surgery.

"Carbolic Acid in Purulent Conjunctivitis," J. G. Rogers, Md., Section on Surgery.

COMMITTEE ON NOMINATIONS.

A brief recess was then taken to allow of the appointment of State Nominating Committees, which were subsequently announced by the Chair.

ADJOURNMENT.

After some further discussion of personal grievances, the Association adjourned until 9 o'clock next morning.

RECEPTION.

The members of the Association were very pleasantly entertained at the White House in the evening, by President Grant and Mrs. Grant. The delegates were introduced by Dr. T. Antisell, and made themselves at home in the various parlors from 8 to 10 P.M.

SECOND DAY—MAY 4, 1870.

The Association was called to order at 9.30 A.M., and on motion of Dr. Atlee the reading of minutes was dispensed with.

SOCIAL REUNION.

DR. GROSS made a motion to the effect that a social reunion be held at the Arlington House to-morrow evening, each member defraying his portion of the expense of a dinner. Carried.

COMMITTEE ON ETHICS.

DR. A. STILLÉ made a partial report from the Committee on Ethics, in favor of admitting the delegates from the Massachusetts Medical Society, but recommending that Society to purge itself of obnoxious members in future. Adopted.

VETERINARY COLLEGES.

DR. ROSS, of N. Y., moved the reconsideration of the motion referring Dr. Antisell's paper to the Committee on Publication. After some discussion that paper was referred to a special committee, with instructions to report upon it.

PERSONAL GRIEVANCES.

An ineffectual attempt was made to renew the discussion of personal grievances among delegates from the District of Columbia. Dr. Loomis of Washington moved that delegates from the District of Columbia be admitted while the question of their eligibility was pending. Lost. On division, Ayes, 107; Noes, 142.

DR. COX moved that the said delegates be refused admission until the report of the Committee on Ethics. Carried.

REPORTS OF COMMITTEES.

DR. T. G. SMITH read the report of the Standing Committee on Publication. Accepted.

DR. GROSS moved that instead of the annual volume, the proceedings of the Association be published in a

monthly or other periodical, to be conducted by the Association. Referred to a select committee of five.

Dr. W. B. Atkinson read the report of the Treasurer. Referred to the Committee on Publication.

BRITISH MEDICAL ASSOCIATION.

Dr. Gross submitted a letter from the British Medical Association, regretting that no delegate could be sent on the present occasion, but conveying the good wishes and cordial sympathy of the British Association, with assurances of welcome to future delegates from their American brethren.

On motion, the letter was accepted and placed on file, and delegates appointed to attend the next meeting of the British Association.

The President announced the following delegates: H. J. Bowditch, J. S. Cohen, E. H. M. Sell, L. Elsberg, M. P. Stephenson, R. R. McIlvain, and H. Lindsey.

COMMITTEE REPORT.

The report of the Librarian Committee was read by Dr. R. Reyburn, Chairman. Ordered to be put on file, and bills audited and paid.

ETHICS.

Dr. L. A. Sayre moved that the present Committee on Ethics be discharged, and matters now before it referred to the new committee on the same subject. Carried.

VETERANS.

Drs. McNaughton and Gethard were invited to take seats on the platform, and came forward accordingly.

EDUCATION.

The Committee on Education was called on for a report, but was not prepared.

MEDICAL LITERATURE.

Dr. J. J. Woodward, U. S. A., presented the report of the Committee on Medical Literature, which was read by the Secretary, Dr. Atkinson. The report commented at some length on the lack of originality in American publications, and the freedom with which American writers avail themselves of the labors of foreigners. Allusion was also made to the large number of periodicals issued in this country, and the small amount of really valuable matter they contained, apart from extracts from European journals, which formed a large part of many of our periodicals. Still some improvement was perceptible in this respect, and faithful observation and careful records were less rare than formerly. The question of copyrights was briefly discussed, the committee being of opinion that it was an important question whether we ought not to secure the early passage of an international copyright law. In the matter of translations much was being done, and valuable material was thus constantly brought before the profession; but this would not be interfered with by the proposed copyright. The committee found much to approve in the recent publication of hospital reports, and the manner in which those reports had been kept. Accepted.

THE REUNION.

At this stage of the proceedings a motion was made to reconsider the resolution of Dr. Gross concerning an Association dinner, the result of which was that the whole subject was laid on the table.

NECROLOGY.

The Committee on Necrology, Dr. C. C. Cox, Chairman, requested more time to complete their report. Granted.

COLLEGE FEES.

Dr. Moore, of Missouri, introduced the following resolution:—

"That all medical schools now recognized by the Association be required to charge not less than — dollars for an official course of lectures, under penalty of non-recognition by this Association and all colleges represented on its floor."

Dr. Selden, of Ohio, moved an amendment that the minimum fee be fixed at one hundred dollars in the resolution as read. Carried.

Dr. Yandell, of Kentucky, thought it as absurd to attempt to fix the price of lectures as it would be to try to regulate the price of horses or beef. There was a great difference in the expenses, rents, etc., in cities and in smaller towns; and the mere fact that colleges charged a given sum for lectures would make no difference whatever in the character of the graduates. He thought these things must regulate themselves; the Association could never control the schools. Some institutions gave their lectures free, and the instruction was as good as any.

After some further discussion the motion was laid on the table.

INSURANCE EXAMINATIONS.

Dr. C. T. Collins, of Mass., introduced the following resolution:—"That whereas the business of life insurance has already become one of great magnitude in the United States, and is daily increasing in importance, affording large profits to those interested; and whereas the responsibilities assumed by the medical examiners do not seem to have been heretofore properly appreciated by the different companies; therefore resolved, that this Association recommend that the sum of five dollars be the lowest amount charged for such examination." Carried.

PROFESSIONAL FEES.

Dr. Horner, of Va., moved the following:—"That the American Medical Association do consider the expediency of a plan of uniform rates of charges, properly adjusted to the wants of the medical profession in the United States, presenting a schedule of the minimum fees, and thereby insuring a legal claim upon the community for the payment of such fees, and also diminishing the embarrassment of the young practitioner." Lost.

SUPPRESSION OF ABORTION.

Dr. D. A. O'Donnelly, of Md., offered a resolution that a committee of three be appointed to report on the evil of abortion, and that the Association denounce and expel all who indulged in the abominable practice. Passed.

A NATIONAL SCHOOL.

A paper on the subject of a national school, by Dr. Heard, of Galveston, was read by the Secretary. Placed on the minutes, to be acted upon next year.

NOMINATIONS.

The Committee on Nominations made the following report:—For *President*, Alfred Stillé, Pa.; *Vice-Presidents*, J. S. Wetherly, Ala.; Henry Gibbons, Cal.; J. T. Hurd, Texas; S. Willey, Minn.; *Assistant Secretary*, J. C. Tucker, Cal.; *Treasurer*, Caspar Wistar, Pa.; *Librarian*, F. A. Ashford, D. C.

Committee of Arrangements.—Chairman, A. M. Sawyer; Dr. Brown, U.S.A.; J. C. Tucker; —— Shurtleff; H. Murray, U.S.A.; Dr. Simmons, Cal.; Dr. Carpenter, Oregon; Dr. Monson, Nevada.

Committee of Publication.—Chairman, F. G. Smith, Pa.; W. B. Atkinson Pa.; J. C. Tucker, Cal.; F. A.

Ashford, D. C.; C. Wistar, Pa.; H. F. Askew, Del.; W. Mayburry, Pa.

Committee on Prize Essay.—Chairman, T. M. L. Logan, Cal.; H. Gibbons; H. H. Toland; Beverly Cole, Casper Lane, Cal.

Place of meeting—San Francisco, Cal.

Time—First Tuesday in May, 1871, at 11 A.M.

THE CONSTITUTION.

The question of amending the Constitution was taken up. A paper on the subject, by Dr. Cochran, of Mobile, was read. The paper contained a resolution excluding all colleges, hospitals, and asylums from representation in the Association. Lost.

ETHICS.

The Secretary read a paper from Dr. Whitehead, of N. Y., moving the abolition of the code of ethics. Laid on the table.

ETHICS.

DR. ALFRED STILLÉ, of Pennsylvania, Chairman of the Committee on Ethics, submitted a partial report, recommending that Dr. C. C. Cox be admitted as a delegate from Maryland, as the charges brought against him were too vague to receive the consideration of the committee.

DR. KELLER, of Kentucky, submitted a minority report from the Committee on Ethics, recommending that Dr. C. C. Cox should not have a seat as a representative from Maryland, as he was a resident of Washington, and moved its adoption.

The majority report was adopted.

Various papers were read by the Secretary, and referred to the appropriate Sections. The Association then adjourned until 9 o'clock on Thursday morning.

EVENING ENTERTAINMENTS.

In the evening the members of the Association met, according to programme, in the United States Army Medical Museum, on Tenth street. The early part of the evening was spent in examining the objects of interest in the Museum, which was highly praised by the visitors.

At 8 o'clock the Association adjourned to the lower hall, from which the desks had been removed and accommodations made to enable those present to listen to lectures from Drs. Otis and Woodward of the United States Army.

DR. GEORGE A. OTIS delivered a highly interesting lecture on excisions for gunshot injuries, of which he exhibited many illustrations, in which the operations made had been successful and the patients recovered. The lecture was listened to with much attention.

DR. J. J. WOODWARD then followed with a lecture on Microscopy, in which he illustrated the power of the artificial lights over the sunlight for micro-photography. Dr. Woodward was frequently interrupted by applause, as the excellence of the illustrations occasioned surprise and admiration.

After the lecture of Dr. Woodward the audience adjourned to the Museum, where the examination of the specimens continued to a late hour.

THIRD DAY—THURSDAY, MAY 5.

The Association was called to order at 9.30 A.M.

ETHICS.

DR. SAYRE stated, that having understood that the Committee on Ethics had so much work on hand that his own case would probably receive no attention during the present session, he had to request that the matter be referred to a special committee.

DR. MADDOX moved that the subject be laid on the table. Carried.

MEDICINE ABROAD.

DR. PINKNEY, United States Navy, representative from the American Medical Association to the British Medical Association, read an interesting report, detailing an account of his visit to, and observations of, the medical schools of Europe. The paper was listened to with much attention. Referred to the Committee on Publication.

NOMENCLATURE.

DR. T. G. SMITH, of Pennsylvania, Chairman of the Committee on Nomenclature of Diseases, made a report, with a resolution recommending the modification of the nomenclature of diseases, as prepared by the Royal College of Physicians at London, in 1869.

DR. UNDERHILL, of New York, submitted a paper on the same subject.

The resolution was debated at considerable length by Drs. Smith, McDaniel, of Alabama, Logan, of Louisiana, and others. The report, together with the resolution, was adopted.

PHOTOGRAPHS.

DR. C. C. COX offered a resolution, which was adopted, for the appointment of a special committee to wait upon the Surgeon-General of the United States, and to request the privilege of duplicating the photo-microscopic slides of the tissues so admirably executed by the industry and skill of Surgeon J. J. Woodward, to be prepared under the direction of said committee, and distributed at a fair price to such medical colleges and institutions as may desire their use.

DR. BEEMISS, of Louisiana, from the Committee on Nominations, reported the additional standing committees for the ensuing year, which report was adopted.

COMPLIMENTARY.

DR. ANTISELL offered a resolution of thanks to the Surgeon-General United States Army for the beautiful and instructive exhibition of last evening, and recommending Dr. Woodward and Dr. Otis to the consideration of the Secretary of War as worthy of promotion for their efforts to advance medical education in the military service.

CONDOLENCE.

DR. C. C. COX then offered a resolution of condolence with the family of the late Alden Marsh, of New York, and that a copy of the same be sent to Dr. Alden Marsh's bereaved family. The resolution was concurred in.

VETERINARY COLLEGES.

DR. STEIN, of New York, offered a resolution that the State and county authorities be requested to aid in the support of veterinary colleges in each of the States by appropriation or otherwise. Adopted.

Also, that one or more veterinary surgeons be associated with other physicians in the boards of health when they are appointed by the Governors. Lost.

Also, that veterinary surgeons be appointed to the army with the rank of full surgeons, and also in the Agricultural Department.

DR. OTIS moved as a substitute that the clause relating to appointments of veterinary surgeons to the United States army be stricken out, and that the Government appoint a veterinary surgeon to the Agricultural Department, with a suitable salary. Adopted.

PROFESSIONAL ADVERTISING.

DR. STORER, of Boston, offered the following:

Whereas, The following votes have been passed by the Gynæcological Society of Boston:

Resolved, That in the opinion of the Gynæcological Society, the vote passed at the American Medical Association at New Orleans, at its session of 1869, condemnatory of cards by specialists in medical journals, is in no sense justified by the obvious reading of that section of the code of ethics which prescribes duties for the support of professional character.

Resolved, That such cards ought not to be considered as public advertisements, nor as intended to invite the attention of individuals afflicted with particular diseases, but simply to remind physicians interested in the affections referred to, and desirous of transferring their charge, that there are gentlemen devoting themselves to their treatment.

Resolved, That while the society would discourage a resort to cards in medical journals by gynæcologists, thinking it far better that professional reputation should rest upon no less a foundation than the publication of scientific memoirs, or the delivery of scientific lectures at medical schools, or to physicians, it yet deprecates any attempt to close by legislation what has become a legitimate means of communication between medical men.

Therefore it is moved,

That the vote of the Association at New Orleans, concerning cards of specialists in journals of a strictly medical character, be and the same is hereby rescinded.

Laid on the table.

MISCELLANEOUS.

A resolution was offered that a committee of three be appointed to wait upon Congress and request them to regulate the quarantine laws. Adopted.

The report from the delegate to the Canadian Medical Association was received, and referred to the Committee on Publication.

The report of the Committee on Communications was adopted, and the committee continued.

Dr. Stewart, District of Columbia, offered a resolution that gentlemen not members of the Association were not eligible to serve on its committees. Tabled.

A resolution was offered regulating the duties of superintendents of hospitals. Adopted.

A resolution was offered that as certain so-called medical works had been published which were injurious to the reputation of the profession:

Resolved, That any person signing his name as author of such work shall be refused membership in this Association.

Adopted.

A VALUABLE DOCUMENT.

Dr. Jones, of the District of Columbia, submitted a tabular statement of all the permanently organized medical institutions and colleges throughout the country, embracing much valuable and interesting information, which, after being read, was referred for publication in pamphlet form.

The Secretary, Dr. W. B. Atkinson, warned the Association that the state of the treasury rendered it very doubtful whether so extensive a publication could be undertaken.

Dr. Storer offered to publish it at his own expense, and furnish it to members of the Association at cost.

On motion to that effect the manuscript was handed to Dr. Storer.

FUTURE MEETINGS.

Dr. Mussey, of Ohio, offered the following:

Resolved, That that clause in the by-laws which provides that every alternate meeting of the Association be held at Washington be repealed, and that in the future the place of meeting should be determined at each session of the Association.

Adopted.

REPORT ON INSANITY.

Dr. Kerwen, of Pa., from the Committee on the Treatment of the Insane, read a lengthy and interesting report, which was referred to the Committee on Publication.

Dr. White, of Buffalo, offered a resolution that the different medical schools of the country establish chairs on mental disorders. Adopted.

PRIZE ESSAYS.

The Committee on Prize Essays announced that there had been received six essays of unusual merit. The prize had been awarded to one on the Treatment of Aneurisms, and Experiments in Securing Arteries by a New Method, by Dr. B. Howard, of New York.

EPIDEMICS.

A resolution was offered that a committee be appointed to report what, if any, legislative means could be taken to prevent the spread of epidemic diseases. Adopted.

ETHICS.

Dr. C. C. Cox inquired if the Committee on Ethics would make any further report on the weighty matters before them.

Dr. N. S. Davis, of Illinois, then submitted, on behalf of the majority of the Committee on Ethics, the following report:—

It appears that the matters reported to your Committee of Registration, and so much of the action of the majority of same committee as relates to the same subjects, embrace the three following subjects:

1st. A charge that a majority of the Registration Committee had refused to register the delegates presenting credentials from several societies, colleges, and hospitals in the District of Columbia, which claimed the right to representation.

2d. Direct charges against the Washington Society and the Medical Association of the District of Columbia, accompanied by a protest against the admission of delegates from those bodies.

3d. Direct charges, which had been lodged with the Committee of Registration, against the National Medical Association of the District of Columbia, accompanied by a protest against the registration of delegates from that society, and from such other institutions as were supplied with medical officers who were members of that society.

In regard to the first charge, your committee find, on investigation, that the Registration Committee have duly registered all the delegates from all the medical institutions claiming representation in the District of Columbia, in accordance with the usages and by-laws of the Association, except the Medical Society of the Alumni of Georgetown College, the National Medical Society, the Howard Medical College, the Freedmen's Hospital, and the Small-pox Hospital, these being the institutions included in the charges already mentioned in the third specification.

It remains, therefore, only to consider the second and third specifications, and your committee ask leave to report on these separately. In relation to the second, we unanimously recommend the following resolution:

Resolved, That the charges offered by Dr. Reyburn, as a minority of the Committee on Registration, against the Medical Society and the Medical Association of the District of Columbia, are not of a nature to require the action of the American Medical Association, the first charge referring to a duty imposed on the society by an act of Congress, and the second referring to a matter which does not come in conflict with any part of the code of ethics.

Resolved, That so far as relates to the Medical Society of the Alumni of Georgetown College, it has been shown to us that the Society has sixty resident members, and is therefore entitled to six delegates.

In regard to the third proposition, relating to the National Medical Society, Howard University Medical College, the

Freedmen's Hospital, and the Small-pox Hospital, we recommend the following:

Resolved, That the duties of the Committee of Arrangements, so far as relates to the registration of members, are purely clerical, consisting in the verification of the certificates of delegates, and a report on the same. If credentials in proper form are presented from any society or institution possessing such organization as would place it *primâ facie* in the list of institutions enumerated in the constitution of the Association as entitled to representation, but against which charges have been made or protests presented, the names of the delegates presenting such credentials, together with the charges or protests in the possession of the committee, should be presented to the Association for its action.

Resolved, That the charges lodged with the Committee of Arrangements against the eligibility of the National Medical Society of the District of Columbia have been so far sustained that we recommend that no members of that society should be received as delegates at the present meeting of this Association.

N. S. DAVIS,
H. F. ASKEW,
J. M. KELLER.

DR. ALFRED STILLÉ, of Pennsylvania, then submitted the following minority report:

The undersigned members of the Committee on Ethics, while subscribing to the greater portion of the report of the majority, feel it their duty nevertheless to dissent from the final resolution recommending the exclusion of the members of the National Medical Society of the District of Columbia from the present meeting of this Association; they offer, therefore, in lieu of that resolution, the following:

Whereas the institutions excluded from representation by the action of the Committee on Credentials, viz, the National Medical Society, the Howard Medical College, the Freedmen's Hospital, and the Small-pox Hospital, are regularly organized as the constitution of the Association requires; and whereas the physicians so excluded are qualified practitioners of medicine who have complied with all the conditions of membership imposed by the Association; and whereas in the judgment of the undersigned no sufficient ground exists for the exclusion of such institutions and physicians from this Association; therefore,

Resolved, That the institutions above named are entitled to representation, and that the physicians claiming to represent them are entitled to seats in the American Medical Association.

ALFRED STILLÉ,
J. J. WOODWARD.

Some excitement prevailed after these reports had been read, and several motions were made simultaneously. Although the yeas and nays were called on the question of rejecting the minority report, the vote was as follows:—Yeas, 107; nays, 85. The minority report was therefore laid on the table.

A motion was made to adopt the report of the majority. Carried.

The Association then adjourned until Friday morning.

ENTERTAINMENTS.

At eight o'clock P.M. the dome of the Capitol was illuminated, and at nine o'clock Mayor Bowen and Mrs. Bowen received the delegates at their residence.

FOURTH DAY—FRIDAY, MAY 6, 1870.

The Association was called to order at twenty minutes past nine. The reading of the minutes was dispensed with, except that portion pertaining to the final vote of yesterday, which, on motion of Dr. Curtis, of New York, was amended to read as follows:

"A motion was then made and seconded that the report of the majority of the Committee on Ethics be adopted. Upon this motion a *viva voce* vote was taken, and the chair decided that the motion was adopted, when two members immediately called for the ayes and noes. Pending the putting the question to the Association of whether the call for the ayes and noes be sustained, the meeting adjourned."

A SUBSTITUTE.

DR. J. J. WOODWARD, U. S. A., offered as a substitute for the resolution of yesterday, regarding the duplication of photographic views of tissues made by himself, the following:

Resolved, That the Surgeon-General be requested to authorize Dr. Woodward to make copies of his photo-microscopic slides, to be distributed at a fair price to such medical colleges and institutions as may desire their use. Adopted.

WOMEN.

The Secretary, Dr. W. B. Atkinson, read a report from the Committee on Ethics regarding the admission of delegates from the Philadelphia Woman's Hospital and Woman's College.

The question of the eligibility of such delegates caused a lively discussion. Dr. Hartshorn, of Philadelphia, spoke in the affirmative. Dr. Cohen reminded the Association that if they admitted these delegates they could not consistently refuse admission to women from the same institutions.

DR. JONES moved that the subject be indefinitely postponed. Carried.

EXCLUSION OF HOWARD COLLEGE.

DR. PALMER, of Maine, offered a resolution of inquiry as to why the Howard Medical College had been excluded from admission to this Association, stating that the institution had been chartered by special act of Congress, and was recognized all over the country as a first-class college.

A discussion took place on the adoption of the resolution.

DR. N. S. DAVIS, of Ill., said if the resolution was withdrawn he, as Chairman of the Committee on Ethics, would give his reasons in writing why the institution was excluded.

The resolution was withdrawn.

RENEWAL OF PRESCRIPTIONS.

DR. R. J. O'SULLIVAN, of New York, offered the following:

Whereas, Apothecaries are accustomed to renew medicines prescribed by physicians without due authority from the physician, thereby doing much injury to patients, and by which many lives have been destroyed; and as apothecaries are unwilling to discontinue the practice except by a general action: Therefore,

Resolved, That this Association take such action as will bring about the discontinuance of the practice.

Referred to a special committee.

PROTEST BY NAVAL OFFICERS.

A paper was submitted protesting, in the name of one hundred and eighteen medical officers of the navy, against the adoption of Dr. Pinkney's report.

DR. PINKNEY made some remarks in defence of his report.

The protest was laid on the table.

A motion was made to refer the whole subject to a special committee of three, to report at the next meeting of the Association. Carried.

INEBRIATE ASYLUMS.

DR. NICHOLS, for the Committee on Inebriate Asylums, asked longer time to prepare a report. Granted.

ADMISSION OF WOMEN.

DR. HARTSHORN, of Philadelphia, offered a resolution that the Constitution be so amended as not to exclude women from membership of this Association. Laid over till next year, according to rule.

ANOTHER AMENDMENT.

DR. POWELL, of Georgia, moved, in amendment to the constitution, that the Association refuse admission to delegates not in good standing in local societies. Laid over for action next year.

DR. SAYRE'S CASE.

DR. HIBBERD, of Indiana, moved that the papers pertaining to Drs. Sayre and Rupanner be referred to their local societies for action thereon. Carried.

INSTITUTIONS FOR INSANE.

DR. LEE, of New York, presented a report on Institutions for the Insane. Referred to the Committee on Publication.

THANKS.

A vote of thanks was tendered to Mayor Bowen for entertaining the Association at his residence last night.

HONORS.

A resolution from committee, declaring Dr. Horace Wells, of Boston, to be the first to make practical application of anæsthetics, was adopted.

THE NEGRO.

DR. JOHN SULLIVAN, of Massachusetts, offered the following:

Resolved, That no distinction of race or color shall exclude persons claiming admission to this Association who are duly accredited thereto.

Laid on the table by a vote of 106 against 60.

ETHICS AGAIN.

DR. DAVIS read the following: In reply to the resolution of the Association calling upon the majority of the Committee on Ethics for the reason why they in their report excluded the delegates from the Medical Department of Howard University, they respectfully state that there is nothing in the report which directly excludes delegates from the said University or any other medical institution in the District of Columbia, except the National Medical Society.

The resolution on this subject, reported by the Committee, is in these words:

Resolved, That the charges lodged with the Committee of Arrangements against the eligibility of the National Medical Society of the District of Columbia, have been so far sustained that we recommend that no member of that society should be received as a delegate at the present meeting of the Association.

It will be seen that the only parties excluded from admission as delegates at the present meeting are the members of the National Medical Society. If the Medical Department of Howard University had chosen to send any delegates who are not members of that society, there is nothing whatever in the report to prevent their being received. In the papers referred to your Committee on Ethics were a list of charges, with specifications in the usual form, against the registration of the National Medical Society. These charges may be clearly stated as follows: 1st—That said National Medical Society recognizes and receives as members medical men who are not licentiates, and who are acting in open violation of sections 3, 4, and 5 of the law of Congress constituting the charter of the Medical Society of the District of Columbia. 2d—That a large part of the members of the National Medical Society are also members of the National Medical Association of the District of Columbia, and are openly and freely violating the rules and ethics of the Association to which they have subscribed. 3d—That they have both in its capacity as a society and by its individual members misrepresented the action of the Medical Society and the Medical Association of the District of Columbia, and used unfair and dishonorable means to procure the destruction of the same, by inducing Congress to abrogate their charter. Each and all of these charges were, in the opinion of the majority of your committee, fully proved by the members of the National Medical Society themselves, who appeared voluntarily before your committee as witnesses. Therefore, if we have any regard to the maintenance of the laws of the land or the ethics of our medical organization, the undersigned could not come to any other conclusion than was expressed in the last resolution recommended by the majority of the Committee on Ethics.

DR. REYBURN was allowed five minutes to explain:—He said he never had violated the code of ethics, and when the colored men applied for admittance to the college to which he belonged, that he offered a resolution providing for their admission. He did not think they should be excluded on account of color. His resolution was not received, and he withdrew from the society, and was one of the leading members in organizing the National Medical Society. If this was a violation of ethics, then he had violated the code.

DR. LOOMIS, of the District of Columbia, said he was a member of the Faculty of Medicine of Howard University, and he could see no reason why he was excluded.

DR. JOHNSON, of the District of Columbia, the President of the Medical Society of the District of Columbia, gave a detailed history of the origin and progress of the difficulties in the local societies for the information of the Association, and replied to a number of questions.

After considerable discussion, Dr. H. R. Storer, of Boston, offered the following, which was adopted:

"That inasmuch as it has been distinctly stated and proved that the consideration of race and color has had nothing whatever to do with the decision of the question of the reception of the Washington delegates, and inasmuch as charges have been made in open session to-day distinctly attaching the stigma of dishonor to parties implicated, which charges have not been even denied by them, though present; therefore,

Resolved, That the report of the majority of the Committee on Ethics be declared as to all intents and purposes unanimously adopted by the Association.

The resolution was then adopted by a vote of 112 yeas to 37 nays; after which the meeting adjourned *sine die*.

REPORTS OF THE SECTIONS.

SECTION ON SURGERY AND ANATOMY.

FIRST DAY—MAY 3.

The Surgical Section met at 3 P.M., and was organized, on motion of Dr. Sayre, of New York, by the selection of Dr. Gross, of Philadelphia, as Chairman, and Dr. Darby, of South Carolina, as Secretary.

The Chairman expressed his thanks for the honor conferred, and announced that the Section was ready to proceed to business. On motion of Dr. Thomas Healy, of Indiana, "That a committee of three be appointed

to draft an order of business," Dr. Healy, of Indiana, Dr. Hammer, of St. Louis, and Dr. Warren, of Baltimore, were appointed.

The Chairman suggested that the names of those composing the Surgical Section should be registered, and on motion of Professor Logan, of New Orleans, a recess of five minutes was given for this purpose. On reassembling it was found that fifty-one members had registered. The committee to draft the order of business presented the following rules, which were adopted:

1st. New matters of general interest to this branch of the profession.

2d. Reading and discussion of original papers referred to this Section.

3d. Oral communications and reports and presentation of cases.

4th. Presentation of new instruments, surgical appliances, and pathological specimens.

5th. The usual parliamentary rules to govern this body.

(Signed)

THOMAS HEALY, Chairman,
A. HAMMER,
EDWARD WARREN.

DR. OTIS, U. S. A., moved "that Dr. Buck's case of plastic surgery be the special order for 5 o'clock on to-morrow, the 4th," which, on being submitted, was adopted.

DR. HAMMER, of St. Louis, presented a paper showing the necessity of establishing a surgical journal. On motion of Dr. Raphael, of New York, the paper was referred to a committee, and Drs. Hammer, Logan, and Wales appointed to act and report upon it.

DR. J. L. LITTLE, of New York, read a paper on "Median Lithotomy," illustrating the mode of operation by drawings, the instruments used, the calculi removed, and the history of cases in his own and other hands. This paper caused considerable discussion, in which Drs. Mussey, Raphael, and Wales participated. On motion, "That the statistical portion only of the paper be referred to the Committee on Publication," it was so ordered.

DR. C. H. OHR, of Indiana, presented a patient, to shqw, as he stated, "excision of the entire ulna, except a small portion of the carpal head, in which entire reparation of the bone followed, giving normal motion at the elbow." The mode of operation, with a history of the case, was verbally stated, and the parts of the bone taken away were exhibited.

The case produced a discussion in which opposing views to those of Dr. Ohr were expressed by the Secretary, Prof. Logan, and Dr. Hammer, who regarded the operation as one for removal of sequestra for necrosis in which the periosteum had not been removed, and from which the bone to that extent could be re-formed. Drs. Porter, Washington Atlee, and Healy, also made remarks in opposition to those held by Dr. Ohr on the re-formation of the ulna. On motion, a vote of thanks was tendered to Dr. Ohr for presenting the case and patient.

Another patient, a boy of ten or twelve years, was shown by Dr. Ohr, with a verbal history of the case, in which, for "necrosis and eburnation," four inches of the tibia had been removed, with reproduction of the bone. Dr. Porter, conversant with this case, opposed the view of "necrosis and eburnation," believing it to be an "osteitis with abscess," for which the bone was removed to the extent stated. The periosteum was preserved, and re-formation of osseous tissue had filled the gap, as shown in the perfect function of the leg in standing or walking.

DR. ATLEE, of Lancaster, followed in some general remarks on the rapid increase of bone in acute periostitis, illustrating this condition by a case in his own practice, dying from a short illness, and where was found great development of new bone in the detached periosteum.

A paper "On a Case of Imperforate Anus" was read by Dr. Healy, of Indiana, in which the history, mode of operation, and result were detailed. Dr. Hammer followed by relating a similar case which he also had operated upon with success, a detailed report of which was published in the Humboldt Medical Archives.

On motion, this paper was referred to the Committee on Publication.

The Section requesting the Chairman to read a paper which he had prepared, Dr. Ohr was called to the chair, and Dr. Gross presented his paper, "On a Form of Neuralgia of the Jawbones not yet Described," giving the cause for this pathological condition, the mode of operation for relief, and a detailed history of four cases. On motion, the paper was referred to the Committee on Publication. In resuming the chair the Section, on motion, adjourned at 5.40 P.M., to meet at the usual hour.

SECOND DAY—MAY 4.

The Surgical Section met at 3 P. M., was called to order by the Chairman, and the proceedings of the last meeting read and adopted.

The report of the Committee on Establishing a National Surgical Journal was received and adopted. A letter from Prof. Kinloch, of the Medical College of South Carolina, enclosing photographs of a patient upon whom he had operated for a large fibro-sarcomatous tumor of the upper jaw, was read, and a motion "That it be filed as a history of the proceedings" was accepted. Dr. Sayre, of New York, stated that he had a paper "On Reflex Paralysis Produced by Congenital Phimosis," which he regretted had been left in New York; but if allowed would verbally state the contents. On motion, it was agreed to permit Dr. Sayre to relate his cases. Several members spoke in reference to incontinence of urine resulting from the same cause, and by a similar operation to that of Dr. Sayre—circumcision—good results were effected. After the general remarks on this subject, it was moved and agreed to, "That Dr. Sayre present a condensed report of his paper to the Committee on Publication."

DR. ROGERS read a paper, illustrated by the history of a case taken from others, "On the Application of Carbolic Acid as a Remedy for Purulent Conjunctivitis." Dr. Pomeroy of New York, and the Chairman, followed in remarks acknowledging that carbolic acid was valuable in such cases, but it was not proven, in the paper presented, superior to the remedies generally used. On motion by Prof. Logan, of New Orleans, the paper was referred to the author for publication in a medical journal, and as having been read before the Surgical Section of the Medical Association. Dr. Cox, of Indiana, read a paper of Dr. B. Titcomb, of Baltimore, giving a formula of a liquid for the preservation of wet anatomical preparations and for injecting subjects. A specimen of a fœtus thus preserved for five years was exhibited. On motion, the paper was referred to the Committee on Publication. Dr. S. T. Hubbard, of New Haven, exhibited a very interesting specimen of uric acid calculi, taken from a cyst of the bladder, which he regarded as unique. On motion, the thanks of the Section were offered for the history, description, and exhibition of the specimen.

DR. ELSBERG, of New York, who was to have reported a case of congenital closure of the rima glottidis, on account of illness was absent. Dr. Raphael, of New York, moved, "That as Dr. Cohen was present, and

was in charge of the paper, that it be read." After the reading of this interesting case, illustrated by a drawing and a wax model, the paper was, on motion, referred to the Committee on Publication.

Prof. Logan, of New Orleans, read a paper "On Reduction of Dislocations at the Shoulder-joint by a New Method," which caused considerable discussion. Dr. Russel, of Ohio, made general remarks on the subject, stating that in this dislocation he was in the habit of making the reduction by applying the force upon the scapula in a direction which tended to place the glenoid cavity upon the head of the bone rather than the head of the bone into the cavity, as generally advised. Dr. Raphael and others expressed views in opposition to the merits of the new mode, to which Dr. Logan replied. On motion to refer the paper to the Committee on Publication, an amendment was offered by Dr. Raphael, that the parts original in the described method should be referred, and the motion as amended was adopted.

Dr. A. B. Stuart, of Minnesota, read a paper on "Extraction by Direct Incision of a Fibro-cartilaginous Tumor of the Knee-joint." On motion, the thanks of the Section were returned to the author.

According to special order, Dr. Buck, of New York, read his paper on a plastic operation of the face, describing by casts the mode of operation, and displaying the condition of parts prior and subsequent to the operation. He presented also a patient upon whom, for similar deficiency of parts of the nose, mouth, and cheek, a similar mode of operation had been made; a plaster cast was exhibited, showing the deformity prior to closure of the parts involved. The description of the instrument for the application of the suture called a "pin or suture conductor" was given, to which, in great degree, Dr. Buck ascribes his success in plastic operations.

A vote of thanks, on motion, was offered by the Section for the cases and patient presented, and the paper referred to the Committee on Publication.

At 5.40, on motion, the Section adjourned to meet at the usual hour.

Third Day—May 5, 1870.

The Section met at the usual hour, was called to order by the Chairman, and the proceedings of the previous meeting read and adopted.

Dr. Charles Carlton, of Conn., verbally gave a report of disease of the eye, for which he had performed extirpation. The specimen was presented, showing a cup-shaped ossified portion corresponding to the fundus of the organ, and resting upon the sclerotic coat. On microscopic examination it was found to be osseous tissue. Dr. Gross remarked upon the interest and rarity of such cases, and Dr. Hammer related a similar case for which he had enucleated the globe, and where true bone was formed, the ossific portion not so great in extent of surface as in the specimen presented, but much thicker. Upon motion of Prof. Logan, "that Dr. Carlton give a full report of the case, and that it be presented to the Committee on Publication," it was so ordered by the Section. On reconsideration of Dr. Little's paper on Median Lithotomy, it was ordered "that the whole paper, and not the statistical portion only," should be referred to the Committee on Publication.

Dr. Otis, as directed by the Association to report on the comparative merits of Syme's and Pirigoff's operations, reported that he had made, as far as statistics of cases were collected, a report which he was ready to read; but as many more cases now being collected would add to the value of the paper, he moved "that the report be deferred until the next meeting of the Association, and that the name of Dr. Quinby be added to the committee." Adopted.

Dr. Quinby read a paper on a modification of Pirigoff's operation, and exhibited three casts taken from three patients operated upon by the mode described. The Secretary reported a case where the same operation had been performed with success by Dr. Turnipseed, of South Carolina, and remarked that in regarding this modification as superior to the original operation of Pirigoff, he had for several years in his course on surgery illustrated it upon the dead body. The Chairman stated that soon after Pirigoff had described his operation, he had suggested a similar modification, and had explained it upon the dead subject to classes. On motion, Dr. Quinby's paper was referred to the Committee on Publication.

Dr. Moore, of Buffalo, read a paper "On the Comparative Merits of Lithotrity and Lithotomy," and described two very ingenious instruments which he had devised for the former operation.

A vote of thanks was tendered to the author, and the paper ordered to be referred to the Committee on Publication.

Dr. Buck followed in general remarks upon the comparative merits of the two operations, giving as a general rule his preference for lithotomy.

Dr. Neftel, of New York, read an abstract of a paper "On the Treatment of Malignant Tumors by Electrolysis," illustrated by the history of a case taken from ten others thus treated. Dr. Hammer and the Chairman followed in opposition to the views expressed. On motion, a vote of thanks was tendered by the Section, and the paper referred to the author for publication in a medical journal.

The Chairman, on account of a special engagement, stated that he was obliged to absent himself, and after congratulating the Section on the work performed, the interest manifested by the members, and the courtesy extended to himself, proposed that Dr. Moore, of Buffalo, be called to the chair. On Dr. Moore taking the chair a vote of thanks was tendered Dr. Gross for the manner in which he had conducted the proceedings of the Section.

Dr. Benjamin Lee, of Philadelphia, read a paper on "Idiopathic Lateral Curvature of the Spine," showing also a modified instrument of his own for correcting this deformity. On motion, a vote of thanks was extended to Dr. Lee, and the paper referred for publication in a medical journal.

Dr. Pomeroy read a paper "On the Use of Glasses in Hypermetropia." The Section voted thanks for the paper presented, and referred it to the author for publication.

Dr. Buck, of New York, moved to adjourn *sine die*, and at 6 P.M. the Section adjourned.

Section on Physiology and Microscopy.

The Physiological and Microscopical Section of the American Medical Association met May 3d.

Dr. F. H. Gatchell was elected Chairman, and Dr. Blatchford Secretary.

Dr. Jos. G. Richardson read an able and interesting paper "On the Cellular Structure of the Red-blood Corpuscle," accompanied by demonstration with the microscope and by diagrams.

Referred to the Committee on Publication. On motion, Dr. Richardson was requested to prepare a paper on the white corpuscle. Adjourned to meet the next day at 3.30 P.M.

SECTION ON PRACTICE AND OBSTETRICS.

DR. JOSEPH KAMMERER, Chairman; Dr. J. C. Jackson, Secretary.

A resolution was introduced by Dr. Hunt, of Conn., on Anæsthesia. Laid on the table.

A paper was read by Dr. Griscom, of New York, "On the Use of Sulphite of Soda, and on the External Use of Glycerine." Accepted.

Several other interesting papers were read before this Section.

SECTION ON METEOROLOGY AND EPIDEMICS.

DR. CATLIN, of Conn., Chairman; Dr. N. S. Davis, of Ill., Secretary.

A paper by Dr. Condie, "On the Diseases of Tennessee," was referred to the Committee on Publication.

A paper by Dr. Hammond, of Ill., was similarly referred.

A communication was received from Dr. H. I. Bowditch, of Boston, reporting progress, and referring to his resolutions of last year, and asking that they be adopted. Adopted, and the whole referred to the Association for sanction. Accepted by the Association.

SECTION ON PSYCHOLOGY.

DR. W. GRAY, of Utica, Chairman; Dr. A. Hartman, of Baltimore, Secretary.

A paper was read by Dr. C. A. Lee, of New York. Paper withdrawn.

THE AMERICAN PHARMACEUTICAL ASSOCIATION.

THE Sixth Decennial Convention, to revise the Pharmacopœia of the United States, met in the hall of the National Medical College, Washington, on the 4th inst.

On motion of Dr. Miller, secretary of the Convention of 1860, Dr. Carson, of Philadelphia, was called to the chair, and Dr. John C. Riley, of Washington, chosen secretary *pro tem.*

DR. MILLER moved that a committee of five be appointed to nominate permanent officers of the Convention, which was passed, and the chair appointed Dr. Squibb, of New York; Dr. Ruschenberger, United States Navy; Mr. Colcord, Massachusetts; Dr. Leon Dove, Massachusetts, and Dr. Jenkins, Kentucky.

DR. HOWARD, of the District of Columbia, moved that the chair appoint a committee of credentials, to consist of five, which was carried, and the chair announced the committee as follows: Dr. F. Howard, District of Columbia; Mr. Proctor, Philadelphia; Dr. R. Amory, Massachusetts; Mr. Ebert, Illinois; and Dr. Maddox, Maryland.

The committee reported the following delegates as duly accredited to the Convention: St. Louis Medical College—A. Litton, M.D.; J. S. B. Alleyne, M.D. Maryland College of Pharmacy—W. S. Thompson, J. Tarris Moore, Louis Dohme. Missouri Medical College—Charles O. Curtman, M.D. St. Louis College of Pharmacy—O. F. Potter, M.D.; Hubert Pruin, M.D.; Eugene L. Massott. Chicago College of Pharmacy—Albert E. Ebert, Henry Biroth, C. Lewis Diehl. Jefferson Medical College—John B. Biddle, M.D.; B. Howard Rand, M.D. Medical Society District of Columbia—Thos. Antisell, M.D.; C. H. Lieberman, M.D.; B. F. Craig, M.D. Medical College of Virginia—J. S. Welford, M.D.; R. S. J. Peebles, M.D. Massachusetts College of Pharmacy—Geo. L. H. Markoe, Sam'l M. Colcord. Medical Society of New York—Caleb Green, M.D.; William Manlius Smith, M.D.; Edward R. Squibb, M.D. College Physicians, Philadelphia—George B. Wood, M.D.; Robert Bridges, M.D.; H. C. Wood, M.D. College of Pharmacy of City of New York—William Hegeman, William Nurgaard, B. W. Bedford. National Medical College—George M. Dove, M.D.; Jno. C. Riley, M.D. Medical Department University of Pennsylvania—J. Carson, M.D.; Robert E. Rodgers, M.D. Philadelphia College Pharmacy—William Proctor, jr., John M. Maisch, Alfred B. Taylor. College Pharmacy of Baldwin University—Martin V. B. Clarke, M.D.; Robert D. Murrey, M.D. Medico-Chirurgical Society, Louisville, Ky.—Dr. Thomas E. Jenkins. Baltimore Medical Association—Dr. T. Clay Maddox. Medical Department Georgetown College—Dr. F. Howard, Dr. J. E. Morgan. War Department, Washington, D. C.—Charles Smart, Surgeon. Navy Department, Washington, D. C.—D. W. S. W. Ruschenberger, M.D. Washington University, Medical Department, Baltimore—Harvey L. Boyd, M.D.; James E. Lindsay, M.D. Massachusetts Medical Society—Dr. S. A. Greene, Dr. Robert Amory, Dr. John Borland. Maine Medical Association—Dr. Henry T. Cummins. Medical Department University, Buffalo—Charles A. Lee, M.D. Medical and Chirurgical Society, Maryland—Dr. W. J. C. Duhamel. Baltimore Medical Association—Dr. J. R. Uhler.

DR. E. LLOYD HOWARD, of Baltimore, and Dr. Thos. Miller, of District of Columbia, were invited to take seats in the Convention and to participate in its deliberations.

On motion of Dr. H. C. Wood, of Philadelphia, it was—

Resolved, That such members of Congress of the two Houses as are graduates of regular medical schools shall be invited to attend the meetings of the Convention and participate in its deliberations, and also the Surgeon-General, U. S. A., and Chief of Bureau of Medicine and Surgery, U. S. N.

The committee to nominate permanent officers reported as follows: President, Dr. Joseph Carson, Philadelphia; Vice-Presidents, Drs. Thomas Miller, D. C., and Wm. Proctor, jr., Philadelphia; Secretary, Dr. John C. Riley, D. C.; Assistant Secretary, Dr. James M. Morgan, D. C.

The committee recommend that the Convention direct the secretary to employ a stenographer to note the proceedings; which report was unanimously adopted.

DR. CARSON, on taking the chair, expressed his thanks to the body in a few touching and expressive remarks, and announced that the Convention was ready to proceed to business.

ALFRED B. TAYLOR submitted the report of the Committee on Revision and Publication of the United States Pharmacopœia for 1860; which was accepted.

The President then called for contributions from societies, when the following were presented: Albert E. Ebert, Chicago College of Pharmacy; H. C. Wood, M.D., College of Physicians, Philadelphia; Wm. Hegeman, New York College of Pharmacy; Alfred B. Taylor, Philadelphia College of Pharmacy; J. Farris Moore, Maryland College of Pharmacy; which were referred to a committee of five to report a plan for the revision of the Pharmacopœia.

On motion of Dr. Lee, it was ordered that all societies not prepared to report have permission to hand in their reports to the Committee of Revision.

The President announced the following as the committee to report a plan to revise the Pharmacopœia: D. Bridges, W. Proctor, jr., Colcord, Walford, and Lee.

On the 5th inst., Dr. Lee, from the Committee to Re-

port a Plan to Revise the Pharmacopœia, submitted a report, providing for the appointment of a Committee on Revision and Publication; also, recommending that the measures of capacity be abandoned in the Pharmacopœia, and that the quantities in all formulas be expressed both in weights and in equal parts by weight. The report was adopted, after being amended that the committee should meet in Philadelphia. The committee was also authorized to investigate any new medicine that may be brought forward in the future, and devise formulas for the appropriate preparations of it.

The delegates from the various institutions then selected a Nominating Committee, who in turn reported the following committee to revise the Pharmacopœia: Dr. G. B. Wood, Alfred B. Taylor, Jno. M. Maisch, Dr. Robert Bridges, Philadelphia; Dr. Edward R. Squibb, New York City; Albert E. Ebert, Chicago, Ill.; J. Tarris Mooré, Baltimore, Maryland; G. F. Markoe, Boston, Mass.; Dr. John C. Riley, Washington, D. C.; Dr. Thomas Jenkins, Louisville, Ky.; Dr. Charles A. Lee, Buffalo, N. Y.; Dr. J. S. Welford, Richmond, Va.; William F. Wentzell, San Francisco, Cal.; W. S. V. Ruschenberger, U. S. Army and Navy.

Dr. B. F. Craig, of the District of Columbia, offered a resolution, which was adopted, "That the Committee of Revision be instructed to include some part of the metrical system in the list of official weights and measures."

Dr. Proctor, of Pennsylvania, offered a resolution, which was unanimously adopted, tendering the thanks of the Convention to the faculty of the National Medical College of the District of Columbia for the use of their building for the purposes of the Convention, which then adjourned *sine die.*

Progress of Medical Science.

A New Application of Compressed Oxygen.—Andrew H. Smith, M.D., of New York, writes:—The introduction of oxygen in cylinders under high pressure, to be used as a remedial agent, enables the physician who has one of these cylinders in his office to apply it in the treatment of throat and lung diseases in a manner which, I believe, has not been heretofore suggested.

By attaching one end of an india-rubber hose to the cylinder, and the other to any one of the different spray-producers, and opening the cock, a spray results which may be made much finer than can be produced with the hand-ball apparatus, and that without the fatigue which the use of the hand-ball occasions. At the same time the operator has one hand free, a consideration which is sometimes very important. With a tongue-depressor in one hand, and the apparatus in the other, it is easy to direct the spray with great precision upon any desired point in the throat or posterior nares.

It is well to use a Richardson's spray-producer, and to have a small hole ground in the bottle near the top, and where it can easily be covered by the index-finger. When the hole is open no spray is formed, but when the point of the tube is exactly in the required position the finger applied to the aperture will at once set the apparatus in action.

The amount of gas required to produce the spray for a considerable time is too trifling to be taken into account. There is scarcely any conceivable case in which the inhalation of the small amount of oxygen escaping through the apparatus would not be rather beneficial to the patient than the reverse.

The local effect of the gas upon an inflamed or congested membrane is gently stimulating.

Demarquay has shown that in passive congestion it gives tone to the vessels and enables them to contract and expel the excess of blood which they contain.

As the spray formed in this way contains oxygen in solution, in addition to what escapes in a free state, its local action is more decided than when gas alone is inhaled.

New Method of Transfusion of Blood.—Dr. Gesellus, a physician of St. Petersburg, says *La Santé Publique*, employs the blood of the cutaneous capillaries for transfusion, rejecting the use of defibrinated blood and venous blood. For this purpose he employs a little apparatus, composed of a very thin cupping-glass; a scarificator with nineteen small blades arranged in five rows, and exposed by pressure upon a button; a small pneumatic pump situated at the superior and lateral portion of the apparatus; a glass transfusion tube hermetically connected at the base of the same apparatus, and capable of containing five ounces of blood, the tube terminating in a small trocar for opening the vein. Cupping glass and tube are enveloped in a jacket of caoutchouc, which, filled with water at 35° C., prevents the coagulation of the blood. The cupping-glass being placed upon the back of the individual from whom the blood is to be taken, and the tube, well closed, falling perpendicularly below, it is kept in position with the left hand, while the right hand produces the vacuum by working the piston. As soon as the individual experiences a painful sensation, a stroke of the palm of the hand upon the button of the scarificator, plunges the blades into the skin and the blood flows. The tube being filled, the stopcock near the trocar is opened, and the trocar being plunged into the median cephalic or basilic vein of the invalid, the blood enters by force of gravity into the vessel. A turn of the stopcock interrupts the operation. A graduated scale upon the glass of the tube indicates at each instant the quantity of blood injected.

Position of the Soft Palate after Death by Hanging.—Prof. Ecker contributes to Virchow's *Archives* (49 Bd., 2 Hef., 1870) an account of a case in which he found the soft palate filling the upper cavity of the pharynx and closing the posterior nares completely.

Aphasia following Scarlatina.—At a recent meeting of the Berliner Medicinische Gesellschaft, Dr. Eulenburg exhibited an eight-year old boy, afflicted with true aphasia, consequent upon an attack of scarlatina. The boy was intelligent, and understood whatever was said to him, but was only able to utter two monosyllables, "ach" and "ya," the latter with a broad accent somewhat like "hier." The word "ach" he used for "nein." The trouble was supposed to be the result of uræmic intoxication from nephritis which had developed cerebral œdema with compression of the cerebral capillaries; and the prognosis as to recovery was unfavorable.—*Allg. Med. Cent. Zeit.*, p. 1055.

Benzine in Whooping-Cough.—Dr. Bottari (Lo Sperimentale. *Gazz. Med. Ital.-Lomb.*, No. 45, 1869) recommends benzine as the best remedy in whooping-cough. It is administered in doses of from 10 to 20 drops in mucilage or syrup, with or without the simultaneous inhalation of the same remedy.

On the Exhalation of Organic Matters from the Lungs.—Dr. Cavagnis reports (*Gazz. Med. Ital.-Lombardiana*, No. 26) the results of some experiments instituted under the supervision of Prof. Mantegazza.

The expired air of healthy and diseased people contains a very slight amount of organic matter soluble in water, which is precipitated by permanganate of

potassa and blackened by sulphuric acid. The quantity varies from hour to hour even in healthy individuals.

The expired air of many healthy people, and also of typhus patients, tuberculous patients in the third stage, and patients with intermittent fever, contains neither basteriæ, vibriones, nor any other organized bodies. Fever patients exhale more organic matters than healthy persons, and tuberculous patients in the third stage more than miasmatic patients. The organic matters exhaled in 300 expirations of a healthy young man, or from 10 expirations of 30 young men, may be injected into the cellular tissue of the blood of dogs without injuring their health.

Late Fecundity.—The *Journal de Toulouse* records that Madame X., of Lavaur, aged 60 years, was recently delivered of twins.

Gastric Juice as an Application to Ulcers.—Dr. Pietro Pagello communicates (*Gazz. Med. Ital.-Lomb.*, No. 29) two new observations on the usefulness of the gastric juice of the dog. The first was a miserably nurtured two-year old boy, from the left side of whose sternum an erectile tumor the size of an apple had been removed by ligature. The granulations which appeared on the ulcer were not affected by nitrate of silver, alum, acetate of lead, or the hot iron; but after three applications of the gastric juice it began to heal, and healed without producing any pain, such as attends the use of caustics.

The second case was an obstinate syphilitic ulcer of the glans, which resisted the ordinary outward and inward anti-syphilitic remedies, but took on healthy granulations after the third application, and cicatrized within eight days after the commencement of the treatment.

A Compound Anæsthetic.—C. Sauer, dentist, in Berlin, has lately been employing with success an anæsthetic mixture of nitrous oxide, chloroform, and atmospheric air.—*Allg. Med. Cent. Zeit.*, 72.

Chloride of Lime to Epithelial Cancer.—Dr. Magni relates (*Gazz. delle Cliniche—Gazz. Med. Ital.-Lombard.*, No. 23) three cases of epithelial cancer of the face cured by the external application, several times a day, of a solution of chloride of lime, 1 part to 15 of water; and internally a solution containing about 7 grains in 180 parts of water.

The Scelometer.—It frequently being a matter of considerable importance to distinguish the exact amount of shortening in a given case of fracture, Dr. H. Z. Gill has devised and described (*St. Louis Med. and Surg. Journal*) an instrument for this purpose. It is in the form of a cross. The long arm is from three to three and a half feet, and the cross piece about thirteen inches long. The instrument is divided so as to be a measurer, the lower portion of the long arm being marked off into inches, half and quarter inches. A round-headed screw is placed in the long arm near the cross piece, to which a tape measure is to be attached to make measurements to various points. The instrument is applied by placing the horizontal piece against the anterior inferior spinous processes, so that the perpendicular shall be exactly equally distant from each spinous process. The feet being placed some distance apart, the perpendicular can fall between them, while the horizontal is retained exactly against the processes. The feet are brought together. If one touch at a point higher up or lower down than natural, there must be shortening or lengthening. The instrument permits measurements upon different points of the pelvis or limbs.

Turpentine in Diseases of the Skin.—Profs. Locke and Von Erlach prefer turpentine in herpes tonsurans and mentagra. Cases are reported in which a rapid cure was brought about by brushing oil of turpentine over the diseased surfaces. Locke reports seven cases of surgical erysipelas thus cured in three days; the disease disappears rapidly, and there is an immediate fall in the temperature of the body. He thinks the turpentine destroys the septic material at the inflamed surface.—*Physician and Pharmaceutist.*

Case of Doubtful Diagnosis of Presentation in Cases of Labor.—Dr. Goodell reported a case of labor (*Trans. of the Coll. of Phys., Phila.*). The child was a male, the mother a healthy primipara, and the labor normal; position L.A.A. At an early stage of the labor the liq. amnii dribbled away, but so green in color as to lead to a suspicion of a breech presentation. After birth this green fluid was found to proceed from the child's mouth, whence it continued to ooze for five days. Taking hardly any nourishment, the infant lingered for three weeks in a state of rigid episthotonus, and died a loathsome mass of ulcers.

Stricture of the Rectum.—Mr. Nunn has long been convinced that non-malignant strictures of the rectum are mostly syphilitic. He is inclined to attribute this to catarrh of the rectum, just as stricture of the urethra follows gleet. Almost all patients with non-malignant rectal stricture are females. Mr. Paget, in describing the chief features of syphilitic disease of the rectum, notices the cutaneous growths about the anus, almost always seen with it. These are growths from the skin, smooth, and flattened from side to side by mutual apposition. A thickened and indurated condition of the lower part of the rectum is met with, with ulceration of its mucous membrane, and a narrow stricture sometimes exists about 1½" from the anus. In cancer the anus is free from disease, in syphilis never; in syphilis the ulceration comes quite down to the anus. Iodide of potassium is of little good; mercury, cautiously administered, is often beneficial. The stricture should be incised and bougies used diligently, but very cautiously.—*Med. Press and Circular.*

Uterine Injection in Premature Labor.—Dr. Garraway, England, in a lady with narrowing of the pelvis, induced labor at 7½ months by passing in a silver catheter between the cervix and membranes, and injecting a pint and a half of warm water. In six hours the head was in the perineum.

How Pus is Formed.—We gather from a long report, lately presented to the Academy of Medicine of Paris by M. Vulpian, that much reliance may be placed on the theory of Cohnheim. It will be remembered that the latter maintains that pus-globules are simply extravasated leucocytes of the blood. M. Vulpian and M. Hayem carried on experiments in pericarditis, encephalitis, myositis, anal fistula, in cases of small-pox, &c., and they conclude that Cohnheim's theory is worthy of great attention.—*Lancet.*

Counter-Irritation in Eye Disease.—Dr. Furneaux Jordan says that counter-irritation is the great remedy for inflammatory disease of the eye. As a rule, gonorrhœal or purulent ophthalmia or ophthalmia neonatorum may be checked instantaneously by a broad horse-shoe of smart counter-irritation to the forehead, temple, and cheek; and acetum lyttæ, arg. nit., or iodine, may be used. The treatment is much more certain and rapid than any nitrate of silver treatment, however carefully conducted.—*Lancet.*

Treatment of Orchitis.—Dr. Besnier, of Paris, says that he uses cloths saturated in concentrated infusion of digitalis leaves in orchitis, with good effect.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

THE AMERICAN MEDICAL ASSOCIATION.

THE late meeting of this Association in Washington was one of the largest that has ever been held. We regret to say that it was not in other respects one of the most satisfactory. The work before the Association during its brief annual sessions is very considerable, and that work cannot possibly be done well if there is any waste of time in profitless discussion. At the recent meeting the time was almost monopolized by questions relating to the admission of delegates from the District of Columbia. These questions were of a local and personal character, and when once the gentlemen interested were allowed to make verbal explanations, there was so much ground to go over, so much accusation and so much denial, that the question occupied about nine-tenths of the time and attention of the Association. We are far from underrating the importance to the individual of his professional character, or the injury that might be done him by an unjust exclusion from membership in the Association; but if the Association were to resolve itself into a committee of the whole on every case of doubtful credentials, there would evidently be an end to all other business. The committees in such cases should be so fully informed that the Association could judge of the facts without personal explanations by the parties accused. In the case of which we speak, nothing whatever was accomplished by the tedious discussion indulged in. The reasons given by the committee for their opinion settled the question at last, so far as it was settled at all, but that was not until the hour of adjournment had arrived. In the meantime the impression made upon the public was one anything but favorable to the dignity of the profession. An assembly of representative medical men should of all others be characterized by harmony and deliberation; and we cannot but regret the warmth of feeling manifested by some of the gentlemen interested in the discussion referred to. The prevalent idea that the question hinged entirely on the admission of the negro to membership is a serious error. The negro was the original cause of dissatisfaction in the Washington Society; but it was the subsequent conduct of the dissatisfied members that, in the opinion of the majority of the committee, rendered those members inadmissible to the Association. One result of the unfortunate affair was the repeal of the by-law designating Washington as the place of meeting every alternate year. This, from the present stand-point, is probably well, for should the Association meet there again, within two years, there would very likely be a repetition of the same scenes that marred the pleasure of the recent meeting, and rendered it comparatively barren of good results.

Apart from the local troubles referred to, the utmost good feeling prevailed among the members, and not even the resolution concerning race and color called forth the least manifestation of a sectional spirit. This augurs well for the future; and the next meeting, on the shores of the Pacific, will mark a new era in the history of the Association.

The actual business transacted by the Association was not very great. Many important subjects came up for a few moments, and were put aside to make room for reports or discussions on ethics or credentials. A motion to regulate the fees charged by medical colleges, making one hundred dollars the minimum fee for a full course of lectures, gave rise to a somewhat animated discussion. This is a point on which the Association clearly cannot interfere, whatever it may be able to do towards elevating the standard of requirements. The schools, however, will not recognize the infallibility of the Association. The question of a national college of medicine was brought up, but its discussion was deferred to another year.

A highly interesting paper on veterinary colleges had been prepared in committee, giving valuable statistics in regard to the lower animals and their diseases. Dr. Antisell was interrupted during the reading of this paper, which was at last referred to a committee. It is matter of regret that no time could be spared for the consideration of a subject of such vast and general interest, and one hitherto almost entirely neglected by the profession.

The adoption of a resolution in favor of establishing chairs of psychology in the various medical schools will, it is to be hoped, cause more attention to be devoted to that branch of medicine. In this connection we may refer to the full and admirable report presented on the treatment of the insane, to which, for want of space, we are unable to do justice in our sketch of the proceedings.

The report of the Committee on Nomenclature of Diseases deserves special attention. They have carefully examined the British system, and are of opinion that a system better adapted to the wants of the American physician could be prepared by a committee for that purpose. It is desirable that nothing be done hastily in this matter. It will only add to existing difficulties if an incomplete nomenclature is urged on the profession; and the committee very wisely recommend that,

before adoption by the Association, the proposed system should be submitted to the practitioners of the United States for their approval, and in order that they may make corrections or suggestions as to its improvement. It is certainly much to be desired that we should have a uniform nomenclature, and if it were possible to have it uniform in this country and Europe, it would be so much the better. Thus far, we believe, the so-called British system has been adopted only in England, and not even in other parts of Great Britain.

The entertainments given in the evenings by the President, the Surgeon-General, and the Mayor of Washington, tended very materially to make the time pass pleasantly, and to promote that fraternal and social feeling which it is one of the objects of the Association to encourage and develop.

Reviews and Notices of Books.

A Hand-Book of Operative Surgery, with fifty-four steel plates and numerous illustrations on wood. By John H. Packard, M.D. Philadelphia: J. B. Lippincott & Co., 1870.

The object of this hand-book is simply to furnish clear and concise directions for the performance of all ordinary surgical operations. The author announces in the preface that there is no room for the discussion of symptoms, diagnosis, or general treatment, except so far as they may influence the choice of operative measures. The work is essentially a practical one, and as such it will be found complete and satisfactory. Its distinguishing feature is abundant illustration, and in this respect it is unequalled by any hand-book with which we are acquainted, though the steel-plate engravings appear to be the same as those issued in Smith's work on Surgery, in two volumes. These engravings constitute the best part of the hand-book, and represent the various stages of the principal operations so clearly as to require little explanatory text. The descriptions, however, are all that could be desired; and to students, and practitioners who have not the frequent opportunity of witnessing practical surgery, the volume before us will prove of unquestionable value, while as a book of reference, especially in surgical emergencies, it will probably replace many of the incomplete hand-books that have preceded it. It would require a very large volume to convey the same amount of information without the aid of the beautiful engravings that render this little book so useful and attractive. The chapter on the eye and its appendages is particularly full and rich in illustration. The ligation of arteries is also treated of in a manner peculiarly lucid. Regarding such operations as lithotomy, amputation of the foot, &c., the different views of distinguished surgeons are described and illustrated, while the opinions of the author are expressed with becoming modesty and reserve.

Intra-Uterine Injections in Suppurative Endometritis.—M. Hervieux, physician to the Paris Maternity Hospital, has published (in the *Bulletin de Thérapeutique*, Feb. 15th, 1870) six cases of this complaint, in recently delivered women, treated by intra-uterine injections of camomile infusion, sharpened with liquor sodæ chlorinatæ. The double-current canula was used, and the result was extremely favorable in all the cases.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 13, 1870.

Dr. J. C. Hutchison, President, in the Chair.

(Continued from page 119.)

LOCALIZED HYDRO-PNEUMOTHORAX.

Dr. Janeway exhibited a specimen, taken from a male patient, 48 years of age, who died in the Charity Hospital, March —, 1870. He had been a patient in the hospital for three months previous to his death. Only a partial history of his case, as of the next, could be presented, owing to a loss of the record book of the division. Before coming to the hospital, Dr. McGay, of the house staff, informed Dr. J. that he had been suffering in the Penitentiary Hospital with cough, dyspnœa, and such prostration as to confine him to bed. A first examination of his chest, early in the winter, revealed marked retraction of the right side, with absence of expansive movement,—this retraction, by measurement, amounting to 1½ inch,—dulness on percussion, except at the apex (where cracked-pot sound existed), hollow breathing and gurgles at apex toward axillary region, and bronchial breathing and bronchophony, with large moist râles anteriorly and posteriorly on this side. The lower border of the liver was somewhat raised. Dr. J. did not at this time carefully examine the axillary region. The other lung presented nothing special. Three weeks previous to his death his attention was again called to him, as his breath had acquired a gangrenous odor and his sputa had become very offensive.

An examination now showed no alteration in the size of the right side, but at the apex and in upper part of axillary region he detected amphoric breathing and metallic tinkling, and on succussion a faint splashing sound. Posteriorly the bronchial breathing was still audible. The man at this time was very weak, expectoration and breath fetid, and the former moderately copious; his pulse was frequent and his face pale and earthy looking. The diagnosis had at first been fibrous induration of the right lung, with a large cavity at the apex. But when apparently these other phenomena developed, then it was considered that a small gangrenous cavity had given way, and produced a localized hydro-pneumothorax in the axillary region. The patient lived for three weeks and died finally of asthenia.

The autopsy showed the right lung and pleura (which were presented) in the following condition:—

The costal pleura was very much thickened, and adherent to the visceral layer anteriorly and posteriorly. The adherent portion, anteriorly, measures about two inches in width. In the axillary region there was a sac formed between lung and pleura which contained air, a thin bad-smelling purulent fluid, and several calcareous plates of large size, some of these adhering to the costal pleura, others being free in the sac. In the upper lobe of right lung there was a small, smooth, round opening, situated at its outer surface at about its middle. The lung being placed in water, bubbles of air could be forced through this opening by a bellows placed in the trachea.

The anterior portion of the right lung was retracted from the margin of the sternum, and its position occupied by the distended left lung. This portion of lung was compressed and somewhat indurated. The inter-infrascapular and part of scapular region were occupied by lung for a good part in a state of fibrous induration, and the pleural surfaces were firmly adherent.

The left wing of the diaphragm presented a calcareous plate three inches in diameter. There was no lesion of the other viscera.

CYST CONTAINING BLOODY SERUM FORMED UNDER THE CAPSULE OF THE KIDNEY.

This specimen was taken from a male patient, 35 years of age, admitted to the Charity Hospital, January —, 1870. When first admitted he presented the signs and symptoms of Bright's disease, swelling of limbs, etc. After a short time he recovered sufficiently to be up and around the ward. About ten days before his death, March 28th, he was attacked with pneumonia of the lower lobe of the left lung. "I had my attention called to him the day before his death. He had then dulness on percussion over the lower lobe of left lung, bronchial breathing and bronchophony over its upper half or two-thirds, and absence of respiratory murmur and vocal resonance below. These signs were not altered by change of position, and taken together with symptoms, showed plainly enough a pneumonia of the upper portion of the left lower lobe; but the point in diagnosis lay in regard to the condition of the lower part, to my mind—whether it were fluid in moderate amount or plugging of bronchi with consolidation.

"The abdomen was not examined at this time, and the record book being lost I cannot say that it had been previously.

"The autopsy showed hepatization of the upper part of the left lower lobe, the lower part being firmly bound down by old pleuritic adhesions, and somewhat compressed also by the elevation of the diaphragm by an abdominal tumor. The bronchi were pervious. On opening the abdomen a tumor the size of a fœtal head was discovered occupying the left lumbar and hypochondriac regions, and reaching anteriorly as far forward as the umbilicus. The spleen was pushed upwards and forwards, so as to occupy the left infra-axillary and mammary regions. The descending colon crossed the anterior and upper border of the tumor, and was somewhat constricted. The stomach had contracted such firm adhesions to the tumor by its lower border, that in separating them the wall of the sac was torn and a bloody serum escaped. Several knuckles of the small intestines were also quite firmly attached to it. On removal of the tumor it was found to be formed of a sac, whose wall was nothing more than the true capsule of the kidney greatly thickened, containing a large amount of bloody serum. The capsule of the kidney can be seen still adherent to the surface of the kidney by a few firm bands at the sides, but for the most part is separated from it. The surface of the kidney was white, but mottled of a red and yellow color by numerous deposits of pigment. This kidney, as its fellow, is a sample of the large white kidney, lay at the bottom of the cyst, and is moderately enlarged. It presented evidences of waxy degeneration, but the epithelium of the tubes was also evidently diseased. As regards the mode of origin of this cyst, it seems probable that a hemorrhage at first produced a partial separation of the capsule, and that subsequently an accumulation of serum increased the amount of separation. I regret that the fluid was not examined chemically. The ureter of this side was pervious.

"An examination of several works on pathological anatomy, etc., did not result in the discovery of a record of a similar lesion."

STATED MEETING, APRIL 27, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

ULCERATION OF ŒSOPHAGUS.

DR. JANEWAY exhibited a specimen of ulceration of œsophagus, taken from the subject of a coroner's autopsy at Bellevue Hospital. He had been brought there on the 5th of April in a state of collapse, with emphysema of the cellular tissue of the neck, arms, face, and thorax. His breath smelt very strongly of whiskey. No history could be obtained from him, and he died one hour after his arrival. On a post-mortem examination, his brain and its membranes were found normal. The larynx and trachea were healthy. The mucous glands of the pharynx were enlarged.

The left pleural sac was nearly filled with a brownish fluid, on which floated numerous drops of oil, and in which were pieces of meat, potato skins, etc., having a strong odor of whiskey. The lung of this side was compressed. The right pleural sac contained a small amount of turbid serum and flocculi of lymph. The lung was normal, but the pleura of its lower lobe was coated by recent exudation.

The œsophagus at its upper portion presented a few follicular ulcerations. On the left side of its posterior surface was a rent $1\frac{3}{4}$ inch long, slightly involving the stomach at its lower end. The edges of the rent were mostly smooth. The direction was longitudinal. The posterior mediastinal tissue was of a brownish-black color, shreddy, and partly digested. This condition extended almost to the bifurcation of the trachea. In this tissue the stomach contents were found, and it had a strong odor of gastric juice. The pleura covering posterior mediastinum over eighth vertebra on the left side presented a ragged rent capable of admitting the ends of two or three fingers. On the right side the corresponding portion of pleura was in a sloughy condition.

The cellular tissue of the eyelids, neck, arms, and thorax were emphysematous. The stomach and other viscera were normal. There was an excoriated bruise on the back over each scapula, but no other marks of injury.

MYELOID DISEASE OF SUPERIOR MAXILLA—RECONSTRUCTION OF ORBIT.

DR. MASON exhibited the patient from whom he had removed the entire right superior maxillary bone for myeloid disease, the specimen having been presented at the meeting, Jan. 26 (vide MEDICAL RECORD, vol. v., p. 18). The parts had entirely healed, there were no evidences of reappearance of the disease, and a new bony floor to the orbit had formed from the periosteum, which had been purposely left in that locality.

SUDDEN DEATH FROM CARDIAC DISEASE.

DR. FINNELL presented some coroner's specimens, for which he was indebted to Dr. Joseph Cushman. The first was an hypertrophied heart, portion of the liver, and gall-bladder, removed from a gentleman fifty-two years of age. He had been for several years past a victim of asthma, and on returning home one evening complained of feeling very badly; but as this was by no means a very unusual occurrence with him, no particular anxiety was occasioned in his family. He retired at his usual time, and was found dead in his bed the following morning. At the coroner's inquest the heart was found hypertrophied, with thickening of the attached portion of the aortic valves. Both lungs were œdematous throughout. The kidneys and liver were fatty, and the gall-bladder was enlarged to three times its normal size, and contained two calculi, lodged

respectively at the neck and fundus. The viscus was filled with a quantity of clear and colorless mucus. The patient did not at any time complain of jaundice.

Dr. Sands was of the opinion that the cystic duct alone was obliterated, which condition of itself explained the absence of jaundice.

RUPTURE OF AN ANEURISM INTO LUNG TISSUE.

A second specimen by Dr. Finnell was an aneurism of the aorta removed from a woman aged 45. She applied for work at a residence in Fourth street, and while engaged in sweeping up-stairs complained to one of the workmen of feeling faint, and in the course of five minutes after dropped down dead. During this time she coughed up large quantities of blood. At the autopsy an aneurism of the aorta was discovered, which had burst, discharging its contents into the lung tissue. Granular kidneys and fatty liver were also found. It is perhaps unnecessary to state that the deceased was of intemperate habits.

EXTENSIVE PULMONARY APOPLEXY.

The third specimen was a portion of lung tissue taken from the body of a gentleman aged fifty-two, who died suddenly while taking a night-supper in a restaurant. The autopsy revealed an instance of extensive pulmonary apoplexy, involving at least one-half of the lung tissue. He was of full habit, and had always enjoyed reasonably good health. The head was not examined, although the suddenness of death was explained by the lesion referred to.

PERIMETRITIS, PERITONITIS, ETC.

Dr. Lewis Smith presented a specimen removed from a primipara who died in one of the public institutions about two months after confinement. There was nothing unusual as regards her labor, and she progressed favorably until the eighth day, when she was seized with chills, which were repeated in the course of the next ten or twelve days three or four times. These chills were accompanied with febrile exacerbations. There was no diagnosis made, as no local symptoms were at the time manifest, save perhaps vomiting, which came on early, and was more or less persistent. This latter symptom was explained by albuminous urine and hyaline casts. She continued in a feverish state, her pulse ranging from 112 to 120. Her general symptoms continued until forty-eight hours before her death, when symptoms of peritoneal inflammation suddenly developed themselves.

The thoracic organs were found, on post-mortem examination, in their normal condition. On opening the abdominal cavity peritoneal adhesions were evident everywhere, and a considerable amount of pus was found in the pelvic cavity. The disease originated in a pelvic abscess which was situated behind and a little to the right of the uterus, which had burst into the pelvic cavity. At first he thought the inflammation to have started in a perforation of the appendix vermiformis, but no obstruction in that tube was discoverable. The abscess involved the caput coli, the lower portion of the ileum, and also extended so as to press upon the rectum, and here there was found a very small opening through which pus could be made to escape on pressure. In his opinion it seemed as if the patient might have been saved if an examination had been made, a bulging of the gut discovered, and an opening made to give exit to the discharge. This was the second post-mortem examination that he had made within three months, that had occurred under similar conditions.

THE DURATION OF THE RED HEPATIZATION OF PNEUMONIA.

A second specimen exhibited by the same gentleman had a special interest in regard to the question of duration of the red hepatization. It consisted of the heart and lungs taken from a child who died at the age of twenty-two months, after suffering for a month with symptoms of pneumonia. One of the parents had died of phthisis; the child was considerably emaciated, and it was conjectured that the pneumonia was due to tubercles. On the 25th of March, about one month before the death of the little one, the attention of the physicians of the Nursery and Child's Hospital was directed to the case. The infant was discovered with an expiratory moan, and examination revealed the entire left lung involved in pneumonia.

The long continuance of this inflammation, as well as its extent, was a matter of interest. It is well known that in a child of that age pneumonia is almost always circumscribed and catarrhal, but when general, as was the case in question, it was croupous. The age would indicate its being catarrhal, and its extent croupous. For the determination of these respective conditions he desired the reference of the specimen to the Committee on Microscopy. The red hepatization, which was still unequivocally marked, had evidently existed as such for a full month.

THE CAUSE OF TUBERCULOSIS.

The third specimen was of more interest, as bearing upon the causation of tuberculosis, and was removed from a little girl ten years old. She had an inflammation, apparently of a scrofulous character, confined to the soft parts of the left thigh. From this pus escaped about ten days before death. No marked general symptoms showed themselves, save diarrhœa and a slight cough, which, by the by, was not noticed until within a few days of her death.

At the autopsy there were discovered recent tubercles in both lungs,—many of these were still gray, while others were in the second stage. It would be recollected that Niemeyer states that the cause of tuberculosis is a cheesy degeneration of the lung. In one place he states that in all cases tuberculosis is preceded by a cheesy degeneration of the lung tissue; but in another place he modifies the statement somewhat, to the effect that cheesy degeneration in other portions of the system gives rise to the same ultimate result. Certainly in the vast majority of cases of infants there is no cheesy degeneration of the lungs preceding tuberculosis, although this change in the bronchial and mesenteric glands is not unfrequently seen. In the case in question, Dr. Smith had examined for the cheesy degeneration, but could discover none even in the glands referred to, although it should be stated that the bronchial and mesenteric glands were crowded with blood.

He believed that recent experiments in Europe tended to establish the fact that tuberculosis might arise from other causes than cheesy degeneration of the glands; for example, confined pus in different localities of the body. In reference to this latter condition, the specimen presented might be a case in point.

The child had a decided umbilical hernia, through which a portion of intestine protruded, which was about seven feet above the ileo-cœcal valve.

TUMOR OF SUBMAXILLARY GLAND.

Dr. Sayre presented a tumor of the submaxillary gland removed by operation. He gave the history as follows:—

Theodore Smith, fifty-three years old, is of healthy parents. His grandfather had a cancer removed from

his underlip. In July, 1869, he had a pimple on the underlip, which was burned out by a "Cancer Doctor." The wound in the lip afterwards entirely healed. In November, 1869, observed a small hard tumor under the middle part, under left side of lower jaw; was movable when first discovered, and continued to be so until the middle of January. At present (April 26, 1870), about the size of a large almond, surrounding the lower jaw, in the region of the posterior submaxillary gland, and apparently attached to the bone. The finger passed inside the mouth, pressing upon the internal projection, gave an indistinct sensation of motion between the tumor and bone. April 26, 1870, assisted by Drs. Yale and Whitehead, I proceeded to remove the mass by an incision lining with ramus of the lower jaw. I found the tumor firmly attached to the periosteum around the lower jaw, extending up, inward, to the floor of the mouth, also very firmly attached to the submaxillary gland, which was removed with the tumor. The periosteum was denuded from the bone, at its inferior and inner border, about one inch and a half—the external lamina of the bone thus exposed was removed by the rougeur. Only one artery—digastricus—required ligature. Had consulted Dr. Wood, also Dr. Olcot, of Williamsburgh, both of whom advised its removal. The facial artery was lifted out of its bed, but was not injured.

The Society went into executive session.

Correspondence.

OPIUM-EATING AND HYPODERMIC INJECTION.

To the Editor of the Medical Record.

Sir—In your issue of March 15th I notice, in an article by Dr. J. H. Bill, on "A New Hypodermic Syringe," with a list of formulæ that may be used in this kind of medication, the following statement, viz.: "When long-continued use of morphia is required, the danger of the habit of opium-eating will be avoided if we inject the opiate." As I believe this opinion to be entirely a mistaken one, and calculated to lead to grave errors in practice, I call attention to the two following cases, which I doubt not are a fair sample of what will occur in others under similar circumstances:—

In December, 1869, Mr. G., æt. about 60 years, in returning by steamer from Europe, was attacked, after exposure to cold, with a severe sciatica, involving the whole of the left limb. From his report, during a tempestuous and protracted voyage, his suffering was extreme. I found him, on arrival, exhausted by severe pain and loss of sleep. Fifteen drops of Magendie's solution were hypodermically administered in the evening, giving him the only refreshing sleep he had had in two or more weeks. The injection was continued in gradually reduced doses about forty times within less than two months, at nearly the same time of day. We both noticed his craving for it, and the restlessness induced by the want of it when omitted, which was only feebly allayed by any substitute. It was only by a strong and persevering effort of the will that he could discontinue the treatment, which was rapidly growing into a settled habit.

The second case (not my own) is a very melancholy one. A gentleman, aged about 40 years, some months ago, having a painful affection about the ankle joint,—a combination of neuralgia and rheumatism as I understood,—was hypodermically treated with morphine by his physician a few times, and was told to repeat the process for himself, as he needed it to combat his sufferings. He has so availed himself of this advice that now he is a confirmed slave to the degrading habit of opium-taking, weak in body and mind. The leg and thigh of the affected side are so thickly studded with the scars of the innumerable punctures of the syringe that scarcely any healthy appearing integument can be seen. He cannot now forego the demand (as I am credibly informed) that his system day by day makes upon this drug, and is as perfectly enthralled by it as if he had been an opium-*eater*, instead of absorbing it through his cellular tissue for all this time. "Verbum sap."

Yours, &c.,

J. G. Sewall, M.D.

New York, No. 854 West 30th Street, May 3, 1870.

A VEHICLE FOR THE INTERNAL ADMINISTRATION OF CHLOROFORM.

To the Editor of the Medical Record.

Sir—The want has been felt by many physicians of a good vehicle for the internal administration of chloroform. Several formulæ have been devised to meet this, but none, that I have seen, do so perfectly. Some are of difficult preparation; others contain sulphuric ether, which is objectionable, and all contain too little chloroform for convenience.

I have lately been using a solution of chloroform in glycerine, which answers the purpose so completely as to leave little to be desired. By a little care in rubbing it up, one part of chloroform by bulk can be dissolved in three of glycerine. This solution is perfectly clear, is bland to the taste, and has but a slight odor of chloroform.

As glycerine is acceptable to almost every stomach, it admits of a wide range of application. It can be taken readily as it is, or can be diluted with water to any extent, without disturbing the solution. Curiously enough, the addition of water immediately increases the smell of chloroform without any precipitation of it. In preparing it, it is best to take one part of chloroform with two parts of the glycerine, add the chloroform very slowly, and rub up carefully. Then put it in a bottle, and let it stand 24 hours. A little chloroform will have deposited at the bottom. Separate this, and rub it up with the third part of glycerine, then mix it with the rest, and the solution is complete. No further separation will take place. Six fluid ounces of glycerine with two of chloroform will give seven of the solution, so that each fluid drachm contains about seventeen M. of chloroform.

From the faint odor of the prepared solution I judge that the glycerine protects it almost entirely from evaporation, although some slight loss may occur while preparing it, which it might be well to make allowance for.

I have used only Squibb's chloroform and a pure article of glycerine, and cannot say how inferior grades may answer.

Having used it in a large variety of cases with entire satisfaction, I can confidently recommend it to others.

Respectfully,

G. Willson Murdock, M.D.

Cold Spring, N. Y., April 30, 1870.

Lupus Treated by Galvano-Caustic.—Drs. White and Hodges, of Boston (*Boston Med. and Surg. Journal*), have successfully treated several cases of *lupus* by galvano-caustic. Dr. Hodges states that the quickness with which a galvanic cautery is got ready for action makes its use very advantageous in surgery.

Medical Items and News.

THE PROFESSIONAL INCOME OF THE LATE SIR ASTLEY COOPER.—This distinguished surgeon, the son of an English clergyman, when swaying the surgical sceptre of England, received in one single year £23,000 from his professional labors; and yet, during the first twelve months after he had settled down in London, and was working as a lecturer on anatomy and surgery, his receipts from private practice only amounted to five guineas.

SUB-INVOLUTION OF THE UTERUS.—The affection of the uterus known as sub-involution was first spoken of by Bailie and Hooper, in 1832. For the practical presentation of the subject we are indebted to Sir J. Y. Simpson.

INSANITY AMONG SOUTHERN WOMEN.—Miss Dix has come to the conclusion that snuff-dipping is the chief cause of insanity among Southern women. She obtained her information while on a tour among the Southern asylums and prisons.

JERSEY CITY CHARITY HOSPITAL.—The report for 1869 shows a total of 215 in-patients, and 543 out-patients.

PUNCTURING THE CHEST IN ACUTE PLEURISY.—Dr. Murchison says that the numerous observations recorded within the last twenty years by Bowditch, Trousseau, Begbie, Gairdner, etc., leave no doubt that, after the failure of therapeutic treatment, puncturing the chest may be safely and advantageously performed in the acute stage of pleurisy, before the effusion has become purulent—(1) when there are any signs of impending asphyxia; and (2) when liquid effusion, even in moderate amount, remains stationary for a week or two in the pleura. He punctures usually between the ninth and tenth ribs, in a line with the lower angle of the scapula. A small trocar is used.—*Med. Press & Circular.*

TREATMENT OF PURPURA.—Dr. Bauer (*Deutsche Klin.*) adds his testimony to that of Henoch, already given, as to the efficacy of secale cornutum against purpura. He employs it in substance 8 to 10 grains, from one to three times daily. Of course no action is exerted upon the blood already effused, but, according to Dr. Bauer, in from one to three days, or at latest after six days, no new spots of purpura are formed, as far as his experience and observation have shown him.

SAN FRANCISCO FEMALE HOSPITAL.—In the lying-in wards of this hospital, during the last eighteen months, there were 90 births, of which 53 were boys and 37 girls. Not a single death occurred, either to mother or child.

THE CLIMATE OF OREGON.—The editor of the *Oregon Medical and Surgical Journal* writes as follows concerning the climate of Oregon:—"Our exemption from the wild sweep of the tornado, which strikes terror to all hearts in its devastating course, should be proof enough that the equilibrium is beautifully preserved by our constant currents of air, ocean-cooled, or warm from the sunny south.

"A like exemption from the lightning's vivid flash and the rolling thunder should teach us that so great is the abundance of life-giving ozone furnished us ready for use, that we need not be pained by witnessing its manufacture." In concluding, he adds that ladies in Oregon "bear their age" better than in any other State in the Union—California, perhaps, excepted.

THE FIRST INSANE HOSPITALS IN THIS COUNTRY.—The first hospital for the insane was that connected with the Pennsylvania Hospital, founded 1751, and now under the care of Dr. Kirkbride. The next in order is that at Williamsburg, Va., opened September 14, 1773. In 1797, insane persons were admitted to the New York Hospital. This branch of the hospital is now known as the Bloomingdale Asylum, and was opened in 1821.

THE SUPPORT OF THE INSANE.—There are 47,000 insane in the United States, unprovided for, except at home; the cost of supporting whom, in asylums as expensive as those now existing, would be $12,000,000 annually.

THE FREQUENCY OF INSANITY.—According to a prominent writer in the *Journal of Psychological Medicine*, insanity occurs most frequently between 30 and 40 years of age, the order of frequency being between 30 and 40, 20 and 30, 50 and 60, above 60, between 10 and 20, and under 10. The hereditary forms are most frequent in youth, the non-hereditary in adult life.

CONGELATION OF PERSONS KILLED BY LIGHTNING.—Dr. Boudin was informed by Gen. Comte de Maistre that some Sardinian sailors killed by lightning in the Mediterranean presented all the signs of death by *freezing.*

EXTRACTUM CYNOGLOSSI, A SUBSTITUTE FOR WOORARA.—Prof. Didichin, of St. Petersburg (*The Druggists' Circular*), has prepared an extract from fresh hound's-tongue, which produces precisely the same effect as the *woorara* or the alkaloid *curarin* on the nervous system of the vertebrata. It is of great importance to find an excellent substitute, when the arrow-poison bears such an extravagant price.

REMOVING CHEMICAL STAINS FROM THE HANDS.—A writer in the *Chemical News* recommends, instead of cyanide of potassium,—which endangers health, and even imperils life,—the use of a concentrated solution of either the sulphate or chloride of zinc as a wash for stained hands, to which some acid is added at the same time. Since most of the salts of zinc are colorless, and soluble in water, the hands become soon quite clear. They should then be washed first with pure water, and next with soap and water.

A CASE OF RATTLESNAKE BITE CURED.—Prof. O. F. Potter, M.D., St. Louis, Mo. (*Buffalo Med. and Surg. Journal*), during an excursion in the summer, was stopped by a harvest hand, who had just been bitten by a prairie rattlesnake of large size. Having no medicines, he scarified the arm, and directed the man to suck the blood with his lips A dressing of moistened clay was applied, and loosely confined by a handkerchief. He next proposed to take him to a neighboring village, some eight or ten miles distant, to obtain means for further treatment. Before starting, the man complained that a stupor was creeping over him, and he ordered him to run half of the way, to overcome the drowsiness and produce perspiration. In the village the usual whiskey treatment was given, with ammonia, but he was surprised to find that a small quantity, comparatively, of the stimulant produced intoxication.

To conclude, the case yielded to treatment, and in a very short time he made a good recovery. The points of the case can be summed up as follows:—1st. The patient was severely bitten by a rattlesnake. 2d. He suffered from, and was completely affected by the poison. 3d. He had no treatment but the drawing of the blood and the clay poultice, for some two or three hours, except the violent exercise; and, 4th. When the whiskey was administered, usually borne in large quan-

tities, intoxication readily supervened, showing, to his mind, an elimination of the virus; and, 5th. A rapid and favorable recovery.

Coal-Gas Poisoning Producing Softening of the Brain.—The occurrence of cerebral hemorrhage and softening, after inhalation of the mixed gases arising from the combustion of coal, is noted by Th. Simon, of Hamburg.

New York Hospital Library.—The extensive and valuable Library of this institution has been removed to No. 13 West 11th Street, near Broadway, and will be open daily from 1½ P.M. to 3½ P.M., and on Monday, Wednesday, and Friday evenings, from 7½ to 9½ o'clock. The Library now numbers over 8,300 volumes; new and important works are added as they appear.

Hard-rubber Capillary Urethral Bougies.—Professor Gouley has recently had made by Mr. W. F. Ford, surgical cutler of this city, very fine filiform bougies, for the treatment of stricture of the urethra, of hard rubber (two-thirds of a millimetre in diameter), which are perfectly flexible, not fragile, and possess the advantage over those made of whalebone by not splitting longitudinally, and the spiral twist at the bladder end is maintained.

Death from the Bite of the Viper.—Dr. Viaud-Grand-Marais reports in *La Santé Publique* two cases of death from the bite of the viper, which occurred in June and July, 1869.

Phréniogénie.—Under this title M. Bernard Moulin has just issued an interesting volume of 300 pages, upon the various causes which might influence the product of conception.

Possible Duration of Pregnancy.—In the course of an action for damages for the seduction of a young woman, the question of the possibly protracted duration of gestation was raised. The alleged father had had no access to the mother of the child later than 301 days before its birth, and he naturally disputed his liability. Dr. Tanner deposed that the ordinary period was 270 to 280 days, but might be exceeded by two, three, or even four weeks. He thought there was no inconsistency in the present case (from April 15th to February 9th—that is, 301 days). He had not known any case himself in which the ordinary period had been exceeded by a week, but he had no doubt there were such cases. He had heard of such. Mr. James F. Clarke deposed that there were cases on record extending over more than 301 days. Sir James Simpson had recorded a case of 310 days. Dr. Barnes deposed that the ordinary period was 271 days. He had known cases of 280 and of 285 days. He thought it very improbable, but did not like to say it was impossible, for gestation to extend over 301 days. It was so improbable that he did not believe it. Dr. Tyler Smith said that the longest period of excess he had known was a fortnight. Dr. Reid—a most accurate observer—had recorded forty-three cases of protraction, the longest of which was 300 days. Dr. Smith considered that case as reliable as any doubtful case could be. The verdict was for the plaintiff; damages, £200.

Spontaneous Combustion.—In the last number of the *British and Foreign Medico-Chirurgical Review*, Dr. Alexander Ogston discusses the truth of spontaneous combustion in the human body. He says that his researches prove that there can be no doubt that the weight of authority is in favor of spontaneous ignition, or, at least, of increased combustibility—two modes of viewing the subject which have been generally combined under the title of spontaneous combustion, or empresmus. Of the fifty-four writers on the subject whom he has been able to discover, the opinions of thirty-five are contained in the sources to which he has had access. Of these thirty-five writers, five are entirely sceptical, viz., Drs. Caldwell, Casper, and Taylor, and the chemists Bischoff and Liebig; three believe in increased combustibility, viz., Dupuytren, Stillé, and Guy; while the remaining twenty-seven, including the illustrious names of Orfila, Paris, Breschet, Devergie, Gordon Smith, and others, believe in the spontaneous ignitability of the human body. One of the most prevalent theories entertained regarding spontaneous combustion has been that hydrogen or other gases were present in the connective tissue and cavities of the body, and that these gases could be ignited by the electrical condition of the body. The other opinion held has been, that alcohol was present in the blood and tissues to such an extent as to be combustible. Dr. Ogston concludes by stating that the recorded cases which can be looked upon as reliable countenance no such doctrine as spontaneous combustion, but point merely to increased combustibility on accidental ignition.

L'Union Médicale of the 15th of February contains an article from the pen of Dr. Bertholle, wherein full details are given of a case of spontaneous combustion. The subject of it was a woman, thirty-seven years old, who was addicted to alcoholic drinks. She was found in her room, with the viscera and some of the limbs consumed, the hair and clothes having escaped. The very minute description of the state in which the deceased was found shows that ignition could not have been communicated from without, and, to all appearance, this is an additional case to those already upon record.

Oxygen First Employed in Disease.—The first case in which oxygen was actually employed as a remedy was one reported by Calliens in 1783. In 1789, Beddoes, Professor of Chemistry at Oxford, published his book entitled "Considerations on the Factitious Airs." To him belongs the credit of being the first to approach the subject without a theory to sustain; and his labors did much toward establishing the true position of oxygen as a therapeutic agent.—*Dr. Andrew H. Smith's Prize Essay.*

New Ophthalmoscope.—Dr. Poncet, of Strasbourg, describes and depicts, in No. 17 of the *Gazette Médicale de Strasbourg*, what he calls his ophthalmoscope à chambre noire, or what we might call a camera ophthalmoscope, intended for the use of those who have not at hand the conveniences of a darkened room. It consists of a copper box composed of two cylinders superposed, one short and broad, and the other longer and narrower. Two covers close them above and below. The lower cylinder has a groove exteriorly, by means of which can be attached a sort of hood of black silk, to be applied to the orbit. It is impossible to give a correct idea of this instrument without an illustration, and we therefore refer those interested to the original article.

Tobacco in England.—The *British Medical Journal* says: In spite of the loud outcry against smoking, made with so much energy a few years ago, and in spite also of the alarming facts which ophthalmic surgeons have recently offered us, the consumption of tobacco does not decrease. The returns show that, during the year just ended, the British population consumed tobacco at the rate of one pound and a third per head. During the last three years there has been each year a slight

increase. The quantity used in 1867 was 41,048,000 lbs.; in 1868, 41,280,000 lbs.; and in 1869 it had risen to 41,719,000 lbs. The increase is probably not greater than increase in population will explain. As regards the deleterious influence of the habit, we should like the attention of those who are investigating it to be directed to the differences in the kind of tobacco used. There appears good reason to believe that some kinds are much more injurious than others, and that the shag —the favorite of the English bar-room, and perhaps of English working-men in general—is the very worst. It is chiefly in reference to disorders of the nervous system—including, of course, all forms of nerve-amaurosis and nerve-deafness—that the problem must be worked out. Unless far greater evils can be proved against tobacco than any scientific evidence has yet hinted at, there is probably little reason to expect that the health argument can even weigh as a feather against the attractiveness of the habit.

Death from Creasote Applied to a Tooth.—*L'Imparziale* relates that a man aged 36 has lately died in the San Maria Nuova Hospital at Florence, from the results of the application of creasote to a carious tooth. Gingivalis and gangrene of the mouth appeared, and death from septicæmia took place in sixteen days. The relator of the fact mentions that, when young, the free application of creasote to a carious tooth which he had was followed by inflammation of the fauces and fever, by which he was confined to bed for three days. These local effects ascribed to creasote are remarkable. We are not aware that any similar cases have been described as occurring in this country.

Methylic Ether as a General Anæsthetic.—Dr. Richardson made a communication at the last meeting of the Medical Society on methylic ether as a rapidly acting general anæsthetic. The methylic ether is a gas, but it is absorbed in very large quantities by absolute ethylic ether, and in the fluid the methylic ether is held with fair stability. The ether is inhaled from a simple mouth-piece, and anæsthesia, sufficiently deep for a small operation, is induced, in some cases, within the minute. Neither symptoms of asphyxia nor of faintness have yet been observed; and one peculiar part of the phenomena of the anæsthesia is, that the operation, as of tooth-extraction, may be conducted painlessly, while the patient is capable of carrying out what seem to be perfectly conscious acts. During the past week several painless extractions of teeth have been performed under the influence of the ether, recovery from its effects being almost immediate, and unattended by vomiting or other disagreeable symptoms. —*British Medical Journal.*

Effects of Light on Vitality.—In a paper read before the French Academy of Sciences, Dr. Dubrunfaut has shown the effects of light on vegetable and animal life. The researches of MM. Gratiolet, Cloez, and Cailletet have, in a great measure, proved that the red rays of the luminous spectrum are those to which the important physiological function exercised by the sun on plants is to be attributed. The leaves act as analyzers of white light; they reject the green rays, which constitute the physical complement of red ones; and it is thus that the various hues under which the organs of vegetation are as seen by us, may be explained. If plants were exposed to green light only, it would be tantamount to their being in the dark. But this light, which the vegetable kingdom refuses, is what is coveted by the animal. Red, the complement of green, is that which, owing to the blood, tinges the skin of the healthy human subject, just as the green color of leaves is the complement of the one they absorb. All kinds of red should be proscribed for our furniture, except curtains. Our clothes, which, in point of fact, play the part of screens, should never be green; while this color, on the contrary, should predominate in our furniture, its complement being reserved for our raiment. In the same way the salubrious influence of woods and forests is a luminous and not a chemical effect. In support of this view Dr. Dubrunfaut mentions cases of patients whose broken constitutions were restored merely by long exposure to the sun, in gardens deprived of trees and other obstacles to light; he quotes the instance of four children that had become chlorotic by living in one of the streets of Paris, and who regained their health under the beneficial influence of the solar rays on a sandy sea-coast.—*Richmond and Louisville Medical Journal.*

Unusual Dislocation of the Head of the Humerus.—The following unusual case of dislocation of the head of the humerus was recently reported by Dr. Eve (*Med. Archives*) to the St. Louis Medical Society:—A lad, 13 years of age, had, about six weeks previously, fallen from an apple-tree and dislocated the head of the left humerus. A physician had attended the case, but the dislocation was still unrelieved. Upon examination the head of the bone was found projecting unusually forward and upward—about two inches in front of the glenoid cavity and three-quarters of an inch above the coracoid process. Ether was administered, and the reduction easily effected, but immediately upon relaxing the extending force the dislocation again occurred. This was repeatedly demonstrated. Dr. E. suspected that there must have been a rupture of the long head of the biceps—there certainly was not dislocation of the tendon—and he had given it as his opinion that the case was beyond remedy. It was the first of the kind he had met with in his extended experience.

Stone in the Bladder.—T. G. Richardson, M.D., Professor of Anatomy, University of Louisiana (clinical memoranda), believes that calculous disease occurs in the United States most commonly in Kentucky, Tennessee, West Virginia, Missouri, and the southern sections of Ohio and Indiana. Taking the boundary line of Kentucky and Tennessee as a starting-point, it progressively diminishes in a northerly or southerly direction. It is exceedingly rare in New England, and along the shores of the Gulf of Mexico it is scarcely more common. In looking over his own practice, he finds but two cases which originated in New Orleans. Although for some years a resident of Kentucky, where he had the opportunity of seeing a great many cases in the practice of his preceptor and personal friend, Professor Samuel D. Gross, M.D., he has never seen the disease in the negro, but is aware that it does occasionally occur in that race.

Syphilitic Inoculation in Dentistry.—J. S. Latimer, D.D.S., N. Y. (*The Dental Cosmos*), in a former communication to this enterprising journal, spoke of the danger of inoculating one patient with the disease of another, and besought dentists to practise great caution, taking care that each instrument which might possibly be contaminated with blood or pus, should be thoroughly cleansed after using.

Recently a very painful illustration of the effects of inoculation has come to his notice, and he deems it advisable to lay the facts before the dental profession, that they may be on their guard.

A dentist (who also practised medicine), resident in a small town in the State of New York, in operating for a patient suffering from a syphilitic difficulty, contracted the disease from absorption of the virus at a

point on one of his fingers where the skin was broken by a hang-nail. Not at first recognizing the disease, and being exceedingly careless with reference to his own health, he employed no appropriate remedies, and was soon unable to continue his practice. The disease progressed rapidly, until, at last accounts, he had suffered paralysis of one-half his body, and was likely to speedily "go the way of all the earth."

If the skin of a dentist's finger becomes broken, it should be covered with a film of collodion or caoutchouc. The "India-rubber" dissolved in bisulphide of carbon answers well for this purpose.

Operative Statistics.—Mr. Nunneley mentions that, in 111 cases of operation for strangulated hernia, 53 being inguinal and 54 femoral, 19 cases died out of the inguinal ones, and 17 out of the femoral cases. In 47 cases of perineal section, 5 died; in 112 lithotomy cases, 98 recovered and 14 died; in 38 cases of tapping for ovarian dropsy, 10 died; and in 25 cases where ovariotomy was performed, 13 died. Of 4 cases of recto-vaginal fistula, 3 failed; of 14 cases of tracheotomy and laryngotomy, 5 died. The tongue has been excised 8 times in Leeds Infirmary, with uniform success as far as the operation itself was concerned. The penis has been amputated 29 times for cancer, with one death, and the testis in 10 cases with two deaths. In 28 cases of operation for aneurism, 2 of the subclavian were fatal; 9 of the common carotid with 2 deaths; 17 for aneurism of external iliac, femoral, or popliteal, of which 9 recovered and 8 died; 23 cases of varicose veins were operated on by placing pins beneath them and twisting thread over them; all were cured. One death occurred from extirpation of the eyeball.

Waterproof Paper for Covering Jars.—Brush over the paper with boiled linseed oil, and suspend it over a line until dry.

Chloride of Gold.—The solution of chloride of gold of $\frac{1}{1000}$ has a remarkable action upon the pacinian corpuscles of the duck or goose, in making microscopical investigations.

Staphyloraphy.—Dr. J. Mason Warren has operated about 100 times. Prof. Mussey, of Cin., reports 4 operations, all on the soft palate. Seven are published by Prof. Goldsmith, now of Vermont. Prof. Hodgen, of St. Louis, and Prof. Miner, of Buffalo, each report three operations. Prof. Markoe, of N. Y., reports two operations, and Prof. Parker, of N. Y., four.

Cases of Plastic Surgery.—In the Leeds Infirmary, during the last 16 years, there were entered 172 cases of plastic surgery. Of these, none were on the lower extremity; 40 were on the upper, of which 32 were cured, 6 relieved, and 2 failed. Those were contractions of the axilla. Fifty were of the neck and face. Staphyloraphy was performed four times, two of the cases being cured, and two much improved. The remaining 77 cases were either of the cheeks, lips, or eyelids.

Eating Hair.—A woman, aged thirty, died lately in Lincolnshire, who had been under medical treatment for some time for a supposed tumor in the stomach. On a *post-mortem* examination a solid mass weighing nearly 2 lbs. was taken from the stomach. It formed a rough mould of that organ, and the termination of the œsophagus. It was found to be composed of human hair, and one of her sisters states deceased was in the habit of swallowing her own hair. It is not often such a case is met with, but in veterinary practice it is more common. We can recall but one or two instances. A horse dying from such a cause is within our experience, and a goat thus destroying itself has been mentioned to us by a friend.—*Med. Press and Circular.*

What Becomes of Old Shoes.—They are cut up in small pieces, and these are put for two days in chloride of sulphur, the effect of which is to make the leather very hard and brittle. When this is found to have been effected, the material is withdrawn from the action of the chloride of sulphur, washed with water, dried, ground to powder, and mixed with some substance which causes it to adhere together, for instance, shellac or any other resinous material, or else good glue or thick solution of gum; it is then pressed into moulds and shaped into combs, buttons, knife-handles, &c.—*Chemical News.*

Chinese Therapeutics.—The Chinese divide medicinal substances into heating, cooling, refreshing, and temperate. Their Materia Medica is contained in the work called the *Pen-taoscang-mou*, in 52 large volumes, with an atlas of plates. Most of our medicines are known to them and prescribed, also mineral waters, with which the country abounds. They also have animal magnetizers, called *Cong-fou.*

They divide their prescriptions into seven categories, viz.:—1st, the Great Prescription; 2d, the Little Prescription; 3d, the Slow Prescription; 4th, Prompt, or Through-by-daylight Prescription; 5th, the Odd Prescription, for fools, madmen, hypochondriacs, and the hysterical; 6th, the Even Prescription, for the wise and good; and 7th, the Double Prescription, for those in the family way.

Each of these recipes is applied to particular cases, and the ingredients that compose them are weighed out with the most scrupulous accuracy.

The physician never pays a second visit unless sent for, and sometimes his services are no longer needed.

Causes of Sterility in the Female.—Joseph Kammerer, M.D., Physician to German Dispensary, in a paper "On the Pathological Conditions causing Sterility in the Female," remarks: Of the patients treated in private practice, 201 in number, 25 are put down as having afterwards given birth to full-grown children. About 100 were either subjected to no treatment, because they presented an unfavorable prognosis, or withdrew from treatment for some reason or other. About 25 are still under treatment at the present time. After deducting these 125, it will be seen that treatment was successful in 25 out of 75, or about one-third of the cases treated.

From this paper it appears that the most favorable prognosis for the treatment of the sterile condition is presented by those cases in which sterility is caused by flexion of the uterus, chiefly retroflexion, and catarrh of the uterine canal; not one case where extensive adhesions were present or lateral deviations existed is marked down as cured.

Magnesium Light.—Late scientific intelligence from Great Britain expresses the belief that magnesium, by new processes of manufacture about to be introduced, will be brought down to a shilling an ounce retail.

At this price its use in lamps, in the shape of a ribbon of the thickness of heavy paper and a tenth of an inch wide, will be decidedly economical.

The magnesium ores and other compounds are unlimited. *Dolomite*, one of the commonest rocks in the Southern States, and extending in a vast range through New Jersey, New York, Western Massachusetts, and Vermont, into Canada, contains 45.65 parts of carbonate of magnesia and 54.35 of carbonate of lime.—*Gas Light Journal.*

A Large Man.—A German, measuring in his stockings 7 feet and 11 inches, resides in Wilmington, Delaware.

Cold Cream.—J. B. Moore, Philadelphia (the *Pharmacist*), recommends the following recipe as very superior:—

Take of Oil of sweet almond, 10½ fluid ounces,
Spermaceti, 3¾ troy ounces,
White wax, 10 drachms,
Otto of rose, 6 to 10 drops.

Melt together, by means of a water-bath, the oil, spermaceti, and wax, and strain through muslin, if necessary; stir constantly until it begins to thicken; then beat it well, and when it has become quite cool add the otto of rose, and continue the beating till the oil is thoroughly incorporated, and the ointment is of snowy whiteness.

Color of Vermilion.—Artists, and others, are aware that the beautiful color of vermilion (cinnabar, sulphide of mercury) has a tendency, especially if it has been mixed with white lead, to become blackish brown and very dark colored in a comparatively short time. This tendency of the vermilion is altogether obviated if, previous to being mixed with oil, it is thoroughly and intimately mingled with about one-eighth of flowers of sulphur.—*Druggists' Circular and Chemical Gazette.*

The Vision of Animals.—M. Paul Bert has recently been experimenting on this subject, and has published his results in Brown-Séquard's *Archives de Physiologie.* The method he adopted was to place a number of the little daphniæ, so common in our ponds and cisterns, into a small vessel the interior of which was well blackened, and into which light could only gain access through a narrow slit. The daphniæ distributed themselves tolerably equably through the darkened vessel, but on transmitting a ray of ordinary light through the fluid they immediately gave signs of agitation, and grouped themselves in and around the illuminated path of the ray. On interposing a screen they rapidly dispersed. M. Bert next proceeded to try the effects of variously colored rays; and he found that the same agitation and the same grouping occurred whatever might be the color of the ray transmitted. At the suggestion of Dr. Krishaber, he transmitted several separate beams of different color through the same vessel, and found then that the animals collected chiefly in the yellow, green, and in that portion of the spectrum which was slightly tinted of an orange color. A considerable number were also seen in the red ray, fewer in the blue, and less and less numbers in the violet and ultra violet. From these and other experiments, M. Bert concludes that all animals see the rays of the spectrum as we see them; that they do not perceive any rays that are not perceptible to ourselves; and, lastly, that in the range of vision the difference between the illuminating powers of the differently colored rays is the same for them as it is for us.—*Lancet.*

Punishment to London Bakers in Olden Times.—Dr. Letheby, in one of his lectures on "Digestibilities of Food," gives the following extract from the records of old London, with reference to the adulteration of food by bakers: "If any default shall be found in the bread of a baker in the city, the first time let him be drawn upon a hurdle from the Guildhall to his own house, through the great streets which are most dirty, with the faulty loaf hanging from his neck; if a second time he shall be found committing the same offence, let him be drawn from the Guildhall through the great street of Cheepe, in manner aforesaid, to the pillory, and remain there at least one hour in the day; and the third time that such default should be found, he shall be drawn, and the oven shall be pulled down, and the baker made to forswear the trade within the city forever."

It further tells us that William de Stratford suffered this punishment for selling bread of short weight, and John de Strode for making bread of filth and cobwebs.

Sulphate of Copper in Bread.—This substance is used by bakers on the Continent of Europe, as it acts like alum in improving the appearance of bread.

The Doctrine of Non-Union in Cases of Intra-Capsular Fractures.—In the year 1830, and before that period, Sir Astley Cooper had taught the doctrine of non-union in cases of intra-capsular fractures, and it was generally accepted as an established principle at that time. The late Reuben D. Mussey, M.D., LL.D., carried a specimen to England which he believed showed the possibility of such union taking place. Sir Astley on first seeing it said: "This was never broken;" but on examining a section of the same specimen, remarked: "This does look a little more like it, to be sure, but I do not think the fracture was entirely within the capsular ligament." Mr. John Thompson, of Edinburgh, on seeing it, declared, "upon his troth and honor," that it had never been broken. This eminent surgeon, like the disputatious Massachusetts Scotchman, "always positive and sometimes right," was in this instance mistaken, as the principle advocated by Dr. Mussey is now established.

The First Recorded Instance of Tying Both Carotids Successfully.—There is still living in Hanover, N. H., a Mr. Jasen Pettee, who is a living monument of Dr. Reuben D. Mussey's pluck and skill as a surgeon. This man had a large ulcerated and bleeding fungoid on the vertex of his head, which threatened speedy death. Dr. M. tied both carotids, and the removal of the tumor followed in a few weeks. The recovery was perfect, and the case was, according to Prof. A. B. Crosby, the first recorded instance where both carotids were successfully tied. This operation gave Dr. M. great *éclat* both at home and abroad.

The First Recorded Removals of the Scapula and a Large Part of the Clavicle.—A. B. Crosby, M.D., Prof. of Surg. in Dartmouth Med. College, states that it is creditable to the surgery of New Hampshire that the first three operations on record for the removal of the scapula and a large part of the clavicle were done by New Hampshire men. The first of these was performed by his father, Prof. D. Crosby, and the other two by the late Dr. Twitchell, of Keene, and Dr. R. D. Mussey.

Electricity for Lessening Pain in Extracting Teeth.—Dr. Pallas, of Bordeaux (*Dublin Medical Press and Circular*), believing that the failure in the employment of electricity for extracting teeth has been caused by the irregular distribution of this agent, has invented an instrument which he considers will obviate this difficulty.

Genuine Farina Cologne.—Oil of lavender, 4 oz.; benzoin and oil of rosemary, of each 2 oz.; purified alcohol (95 per cent.), 9 gallons; dissolve the ingredients, and add, oil of neroli, oil of petit grains, and oil of lemon, 10½ oz.; oils of orange, limes, and bergamot, 20⅔ ounces; essence of rose geranium, 3 pints. Macerate 3 weeks, and bottle.—*Jour. of Applied Chemistry.*

BLISTERING PAPER.—White wax, 8 ounces; sweet oil, 4 ounces; spermaceti, 3 ounces; turpentine and powdered cantharides, of each 1 ounce; boil for two hours, with constant stirring, in 10 ounces of water; strain through flannel, and, while hot, spread it on paper.—*Jour. of Applied Chemistry.*

DR. LLOYD ROBERTS ON OVARIOTOMY.—Dr. L. Roberts, of Manchester, says that the chief points to be attended to in ovariotomy are: A very pure air in the room—a temperature of 64° Fahr.—a very sparing use of chloroform, methyline, or sulphuric ether; a small incision at first, enlarged if necessary; the incision down to the peritoneum to be made without a director. The first incision may reach to two inches above the pubes. Adhesions to bladder, liver, and intestines are dangerous in the order written, and are to be carefully dissected and bleeding vessels ligatured, cutting off ends of ligatures. The pedicle, when long, may be clamped or tied and returned into the abdomen, or the actual cautery used. Sponges should take away any clots in the cavity of the peritoneum, and silver wire is the best means of closing the wound by sutures, including the peritoneum in the suture; the wound to be supported with crossings of plaster. Patient takes little nourishment for 48 hours. Pain is controlled by opium suppositories. The bowels are to be relieved by an enema on the fifth day, and the catheter used every four hours for some days.

SKIN DISEASES.—Dr. McCall Anderson approves much of blisters in obstinate circumscribed eruptions over the part affected. He uses Smith's "emplastrum cantharadinis liquidum." It is often useful, he says, in lupus erythema and lupus non-exedens. It is the best remedy in alopecia areata, and in ringworm, or chronic eczema. He sometimes uses a solution of iodine and iodide of potassium in glycerine; half an ounce of each to one drachm of glycerine. He praises highly the solution of one drachm of caustic potash to two of water, painted over the surface in eczema. The patient rubs the skin afterwards with a piece of flannel dipped in water until a lather is produced. For ringworm he recommends Mr. Coster's combination of iodine and tar. Pure iodine, two drachms; oil of tar, one ounce; gradually mixed and applied locally. One application, he says, is often enough where the disease is recent. He advises, in ordinary cases of lupus, to penetrate through the lupous deposit by means of a pointed piece of lunar caustic until the healthy tissues beneath are reached. No dressing is required. He also uses the actual cautery in such cases, according to Mr. Hutchinson's plan. Dr. Lipp publishes in the *Arch. für Dermat. und Syph.*, No. 3, 1869, two cases of psoriasis and three of chronic eczema which were cured by hypodermic injections of arsenious acid. In the former the result of the injections was satisfactory, after the internal use of Fowler's solution had failed. The cases of eczema are not so conclusive, as other means besides the injections were used. In the first case of psoriasis eight grains of arsenious acid were injected in forty-eight days, and in the second four grains in thirty-eight days. The author gives minute details respecting the phenomena observed during the injections, and states that he does not mean to infer from so few cases the superiority of the injections over the internal use of arsenic; but he merely observes that in favor of the former he might mention—the certainty of absorption, the non-interference with the organs of digestion, the small doses used, and the short treatment.

GALEN.—This renowned medical man was born 130 years before Christ.

AMPUTATION OF THE RIGHT ARM AT THE SHOULDER JOINT, WITH EXCISION OF A PORTION OF THE SCAPULA, FOR NECROSIS.—Dr. W. H. Hess, Nebraska City, Neb. (*The Chicago Medical Journal*), recently performed an operation of this character on a soldier in the late war, who received a gunshot wound in the elbow joint, for which his arm was amputated at the time. A second amputation was performed two years and three months from the time of the first operation.

The diseased bone being all removed, the wound was well cleansed with a solution of carbolic acid, tents soaked in the same solution left in the cavity; the parts were brought together with the ordinary suture, and cold water dressings sparingly applied. The patient did well, and returned to his home, in Iowa, eight days after the operation. A solution of carbolic acid was injected in the wound every day for three weeks after, to favor healthy granulations. Carbolic acid is, in his opinion, one of the most valuable remedies we possess for diseased bone.

THE RELIABLE ANTIDOTES FOR BINIODIDE OF MERCURY.—The retiring President, J. T. Travers, M.R.C.S.L., in an "Address before the St. Clair and Sanilac County (Michigan) Medical Society," observes with regard to antidotals: "So far as my means of judging indicate, the employment of liquor potassa, solutions of carb. potassa extemporaneously prepared, lime-water followed immediately by bicarb. potassa, and the sulphide of ammonia or potassa, the latter being the better, followed by emetics or the stomach-pump, constitute our chief antidotes."

As albumen forms no precipitate with the biniodide, it is not an antidote, and should not be given.

ELIXIR OF CHLOROFORM.—The following *Elixir Chloroform* is recommended by the Pharmaceutical Association at Washington, D. C.:—

℞. Chloroform, tinct. opi., tinct. camph., ip. ammon. ar., āā. ℥ iss;
Oil of cinnamon, ♏ xx;
Brandy, ℥ ij.
M. S. Half a fluid drachm, more or less.

TO RENDER DECOMPOSED SYRUP OF IODIDE OF IRON CLEAR.—According to M. Jeannel, the addition of $\frac{1}{3000}$th part of tartaric acid renders syrup of iodide of iron clear when decomposed, and removes the inky taste.

WHITE-LEAD DRESSING IN SEVERE BURNS.—Dr. Edwards (*The Leavenworth Medical Herald*) was called to a young girl who was burned to a crisp over the hips, scapula, and posterior part of the arm; the parts below the hips to the knees were red and inflamed, and the space above the hips to the neck also severely burned. With a paint brush he painted the entire burnt surface with white lead and linseed oil. Half a drachm of svapnia was given every thirty minutes; pieces of a linen towel were applied over the entire surface, and saturated with lime-water and linseed oil; and in one hour and ten minutes after his arrival she was asleep. This with lint steeped in the latter preparation, and svapnia occasionally, was the entire treatment. He remarks, in conclusion, that there is no danger of absorption, as it is a physiological fact inflamed surfaces do not absorb.

POSITION OF THE FŒTUS IN UTERO.—An interesting paper was read before the Obstetrical Society of Boston, Feb. 12th, 1870, by B. E. Cotting, M.D., on "Position of the Fœtus in Utero," and from demonstrative evidence laid down the subjoined opinions: At all stages of development, the head lies at or towards the

uterine outlet; the ovum, so far as yet possible to make out, shows the same general position of the embryo; premature deliveries give normal presentations most frequently, if not as frequently as complete gestation. The fœtus lies, or tends to lie, in its mother in a position completely the reverse of that of the patient; and, so far as has been noticed and recorded from the beginning, as certainly at later periods, its face is turned opposite to its mother's face, feet opposite to feet, back opposite to back, abdomen opposite to abdomen, etc., —with a tendency, perhaps, to be cast off prematurely if exceptionally in any other position.

The First Greek Surgeons on Record.—Æsculapius and his two sons, Machaon and Podalirius, are the first recorded Greek surgeons. The father flourished about fifty years before the Trojan war.

Lithotomy First Performed.—The operation of lithotomy was done in Hippocrates' day. This distinguished surgeon died in his one hundred and first year.

New Test for Carbolic Acid.—Joseph M. Hirsh (*The Pharmaceutist*) states that minute quantities of carbolic acid may be detected in solution by adding a drop of the tincture of ferric chloride, when a purple coloration will be perceived. If the quantity present is large, a purple precipitate will be produced, which, upon the addition of glycerine, dissolves with an olive color.

A New Insect Poison.—M. Cloez, one of the gardeners of the Paris Museum, has discovered a complete annihilator for plant lice and other small insects. Take three and one-half ounces of quassia chips, and five drachms of stavesacre seed; boil these in seven pints of water until reduced to five. When the liquid is cool, strain it, and use with a watering-pot or syringe.

Herniotomy.—O. G. Selden, M.D., Shanesville, Ohio (*The Cincinnati Lancet and Observer*), in referring to the recognized standard works on *Herniotomy*, believes that most of the practical rules are correct, and the main difficulty is to properly apply them. Adhesions to the hernial sac are mostly found where the hernial omentum presents all the essential characters of schirrus, at or near the abdominal ring. After dividing the stricture and returning the intestine into the abdomen, it has been his invariable practice to enclose the pedicle of the mass of omentum in a stout ligature at or near the abdominal ring, and cut away the mass below the ligature. He has not seen colicky pains follow such a proceeding, as are recorded by a French author; and in no case was there the remotest symptom of peritonitis.

After giving his opinions and practice with reference to *strangulated hernia*, the two following rules are deduced: When the hernia omentum is much inflamed, or contused, or in a state approaching gangrene, as often happens from the application of undue force in attempts to reduce by taxis, the part should be left in the sac.

When the abdominal ring is much distended, and a large mass of omentum is found within it and the sac, and if the omentum be either in part or in whole hypertrophied, or indurated, without tissue degeneration, the whole may be safely returned into the abdomen.

In the thirty-six cases in which he has operated no anomaly has occurred.

Spiders' Silk.—A bar of iron 1 inch in diameter will sustain a weight of 28 tons; a bar of steel 50 tons, and, according to computation based upon the fact that a fibre only 1-4000 of an inch in diameter will sustain 54 grains, a bar of spiders' silk 1 inch in diameter would support a weight of 74 tons.—*Chemical News.*

Death of Sir James Y. Simpson.—It is with deep regret we have to announce the death, at the comparatively early age of fifty-nine, of Prof. James Young Simpson, one of the most distinguished physicians of the century. Prof. Simpson was born in Bathgate, Linlithgowshire, in 1811. He received his education at the University of Edinburgh, where, in 1832, he took the degree of M.D., closing his undergraduate course with great honor, his thesis before the examiners being a production of extraordinary ability. He began his professional career as assistant to the late Prof. Thomson, and in the course of his duties collected the materials for his "Obstetric Memoirs," afterwards published. In the year 1840 he was appointed Professor of Midwifery in the University of Edinburgh, succeeding Prof. Hamilton in that position. In the year 1847, Dr. Simpson first produced insensibility during accouchement by the use of sulphuric ether. During the same month this anæsthetic was applied by Dr. Morton in this country during the extraction of teeth. Dr. Simpson, after his discovery, devoted much attention to the demonstration of the safety of anæsthetics as employed in obstetrics, subsequently discovering the properties of chloroform, which he regarded as more manageable, and in other respects better than ether in midwifery practice. In 1849, Dr. Simpson was elected President of the Edinburgh Royal College of Physicians, in 1852 President of the Medico-Chirurgical Society, and in 1853 foreign associate of the French Academy of Medicine. In 1856 he received from the French Academy of Sciences the Monthyon prize of 2,000 francs "in consideration of his services to humanity by the introduction of anæsthetics into the practice of midwifery, and the discovery of the anæsthetic properties of chloroform." The professional writings of Dr. Simpson are numerous and widely known. Of his Obstetric Memoirs and Contributions an edition has been published in this country under the supervision of Dr. H R. Storer. His "Contributions to Obstetric Pathology," "Essays on Anæsthesia," and a "Treatise on Homeopathy," have also been republished in this country, with several memoirs relating to the history and antiquities of his profession. Dr. Simpson has done more for the reputation of the Edinburgh School of Medicine than any other one man. He possessed a marvellous natural capacity, with a vigorous constitution, which enabled him to do a vast amount of work. Apart from his official duties, Dr. Simpson had a larger private practice than any other physician in Edinburgh. In January, 1866, Dr. Simpson's distinguished services to humanity received public recognition from the Crown. He was created a baronet, and in the same year received the honorary degree of D.C.L. In 1867 he presided over the Health Department in the Social Science Congress at Belfast, but since that time has led a life of comparative retirement.

Lecture I.

Histological and Physiological Summary.

Before beginning the study of those affections of the nervous system in which motility and sensibility are, singly or together, disordered, it may be well to briefly set forth a few leading points of the

MINUTE ANATOMY AND PHYSIOLOGY

of the cerebro-spinal axis. I must ask you to accept provisionally, as I have done, these statements of structure and function as necessary to a right understanding of the clinical facts which are to form the material of these lectures. Whatever additions or subtractions future investigators may make to them, I do not believe that these postulates will be materially disturbed, bottomed as they are on evidences, direct and indirect, which warrant their being taken as articles of anatomical and physiological faith.

The histologic elements of which the nervous system is built up are of two kinds: (*a*) the gray or vesicular, and (*b*) the white or fibrous. They contain protein compounds and phosphatic fats differently distributed in both kinds. The gray substance is gathered into masses and mingled with the white substance, as in the brain, spinal cord, and ganglia, forming the *nerve-centres*, where peripheral impressions are received, and power is generated and dispensed. The white substance, besides making a large part of those centres, is a chief, if not as was once held the only, element in the structure of the *nerves* or communicating agents which link the headships with the outlying organs. The vascularity of the gray substance is much greater than that of the white, and it contains more water, the proportions of solids to fluid being estimated at 12 per cent. in the gray, and at about 25 per cent. in the white substance.

The *gray* or *vesicular* substance, of a dark reddish-gray color, consists of the *ganglion-cells*, or *-corpuscles*, evolved out of nitrogenous protoplasm, aggregated into spheroidal masses. These corpuscles have every element of a true cell, as: a delicate investing membrane, a pale fine granular matter, a variable amount of pigment, and a spherical nucleus whose outline is more distinct than that of the cell-wall, having amongst its granules a brilliant nucleolus. They vary in shape, and are either originally developed as two distinct kinds, or they undergo progressive changes. The smallest, ovoid or rounded, with a regular uninterrupted contour (apolar), are most numerous in the sympathetic ganglia; the larger ones, of the brain and cord, are polygonal or *stellate*, and have one or more tail-like processes, and are hence called, respectively, *unipolar*, *bipolar*, or *multipolar*. These processes either intercommunicate with those of other cells, or become continuous with the core of the nerve-fibres (Fig. 1).

The *white* substance is made up of *nerve-fibres* or *-tubes*, which are of two kinds: the first kind, and which may be taken as the common type of nerve-tubes in

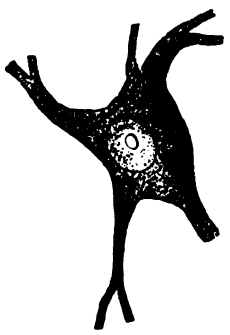

Fig. 1.—Multipolar nerve-cell from anterior horn of spinal cord, with processes, nucleus, and nucleolus.

Fig. 2.—Fresh nerve-fibre.

the cerebro-spinal system, seem, when perfectly fresh, to be clear, transparent, highly refractile threads, in which apparently there is no trace of structure. After a short exposure a change happens, a sort of coagulation taking place, and it appears that each little cylinder is composed of (1) a very delicate investing anhistous membrane, on which there are oval nuclei, within which is an (2) oleaginous matter called myelin, or medullary or white substance of Schwann, whilst in the centre there is (3) an albuminous round or flattened core, or thread, which is the *axis-cylinder* or primitive band. All those nerve-fibres show a double contour, (1) the outer line formed by the sheath, and (2) the inner by the curdled medullary substance, which, breaking up, as it were, into small masses, gives the beaded or varicose look which the fibres soon acquire (Figs. 2, 3).

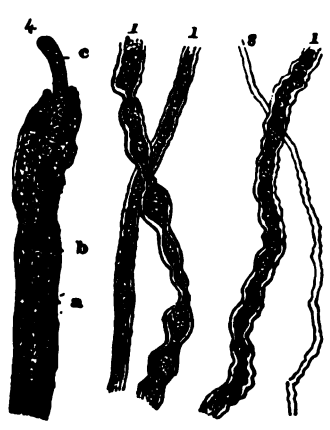

Fig. 3.—1, 1, 1. Double-contoured nerve-fibre of the large kind. 4. Fibre after treatment with chromic acid and carmine. *a*, envelope; *b*, white medullary matter of Schwann; *c*, axis-cylinder thread.

Fig. 4.—Fine nerve-fibre of single contour.

Professors Lister and Turner have shown an essential difference in chemical composition between this tiny protein central thread, and the pearly, viscid, oily pulp in which it is imbedded; and it will be well to bear in mind that in following what is called Dr. Lockhart Clarke's method of preparing nervous tissue for microscopic examination—and which, by the way, originated

with Jacobson, a well-known lithotritist of Copenhagen, and was carried from thence to Germany by Hannover (1840)—the axis cylinder of the nerve-fibre is unaffected by chromic acid, but is deeply stained by carmine; whilst the white substance of Schwann is made opaque, brown, and laminated by chromic acid, but takes no tint from the carmine. This enables an easy distinction to be made between the central and peripheral portions, a pale, dingy ring surrounding the bright-red carmine-colored point. The size of the nerve-tubes varies from the $\frac{1}{5000}$th to the $\frac{1}{800}$th of an inch in diameter in the trunks and branches of the nerves, whilst they gradually become smaller as they approach the brain and cord.

The fibres of the second kind, mingled in with the cerebro-spinal nerves, and a chief part of the trunk and branches of the sympathetic nerves, are much finer than the first; of a pale or grayish hue, they have a single contour, and their contents seem uniform. Their probable difference is the absence of the medullary sheath (Figs. 3, 8, and Fig. 4), and they are probably identical, histologically, with the axis-cylinder of the large tubes.

The nerve-fibres are gathered into bundles and lie in apposition with each other, but never unite; in the several anastomes which may happen there is no union, but simply interchange. On reaching their terminal points they split up, and the medullated fibres lose their white sheaths, and take on the characters of the smaller pale fibres. The connection between the nerve-fibres and the ganglionic cells is shown in this diagram (Fig. 5). The mode of connection be-

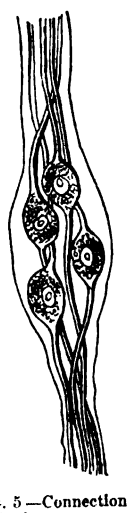

Fig. 5.—Connection of bipolar nerve-cells with nerve-fibres, showing one prolongation continuous with nerve-fibre from spinal cord, and the other with a peripheral nerve.

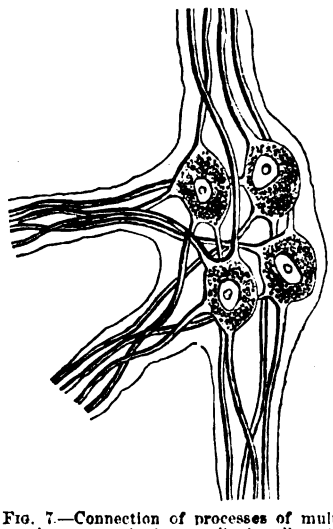

Fig. 7.—Connection of processes of multipolar sympathetic ganglionic-cells with nerve-fibres (after Leydig).

tween them and the nerve-corpuscles of the spinal cord in man is still unsettled, but in the lower animals their relations and course have been more successfully demonstrated, as seen in this diagram (Fig. 6). In the sympathetic ganglia most of the multipolar cells seem, according to Leydig, to send out the same number of processes as there are nerves connected with the ganglion (Fig. 7).

Now all the proper elementary structures of the nervous centres lie together in, or, more correctly speaking, are bound together by, a kind of connective tissue, which Kölliker called *reticulum* and Virchow *neuroglia*. In a thin section of the cord, prepared with chromic acid and carmine, it appears as a homo-

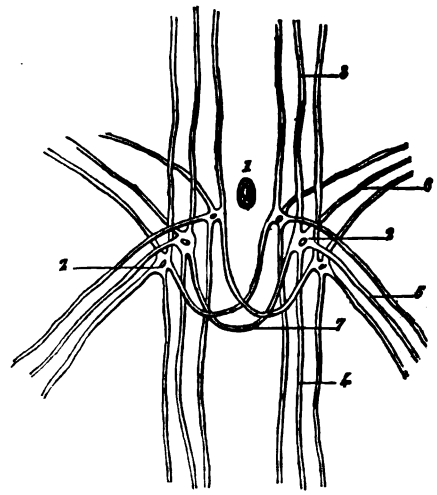

Fig. 6.—Connection between nerve-fibres and ganglion-cells in spinal cord of fishes (after Owsjanikow). 1, Central canal; 2, ganglionic cells; 3, superior prolongation; 4, inferior prolongation; 5, anterior root; 6, posterior root; 7, transverse commissural fibre making connection between the cells of the two sides of the cord.

geneous substance which seems to fill up, like a cement, the interspaces between the nerve-tubes. It is in still greater abundance in the gray substance. It is in excess, too, in the gelatinous substance around the expanded extremity of the posterior horns of the cord, and in the posterior commissure. It is important to recognize the existence of this connective frame-work or gangue, for it is specially interested in some of the lesions we shall have to consider.*

From these summary indications of the composition of the nervous system it would appear to be made up of threads enclosed in sheaths which shield them from lateral disturbance, and corpuscles of unstable matter embedded in protoplasm; the threads gathered into bundles are mostly the outer parts, while the corpuscles with their bed are chiefly the inner or central parts. The threads with their central corpuscle, or gray matter, form the unit of composition of the nervous system; and there are various groupings and combinations of these units.

Physiologically the nervous system is truly composed of three distinct centres, namely:—1st. The cranio-spinal apparatus, which comprehends the peripheral portion or nerves; the cord; the intercranial portion (medulla oblongata, pons varolii, tubercula quadrigemina, cerebral peduncles), and has as an appendage, the cerebellum; 2d. The cerebral apparatus proper, composed of the superimposed hemispheres; and 3d. The apparatus of conjunction, constituted by the optic thalami and the corpora striata. The union of the spinal and cerebral apparatus is mediate, through the interposition of the gray matter of the optic thalami and corpora striata. The anatomical facts which justify such a division have been clearly demonstrated, particularly by Luys (*Recherches sur le Système Nerveux.* Paris. 1865).

There are certain fundamental facts of function connected with these facts of structure that have an express clinical significance in the class of disorders we are treating of, and which cannot, therefore, be overlooked.

* Notes on the Physiology and Pathology of the Nervous System, with reference to Clinical Medicine. By Meredith Clymer, M.D. New York: D. Appleton & Co. 1870.

We may assume generally, as an organic law, that differentiation of structure involves differentiation of function. Now, each of the two substances which enter into the constitution of the nervous system—the gray or vesicular matter, and the white or fibrous—has its proper endowments and duties. The gray matter is creative, dynamic, and mandatory; the white matter is passive and executive. As has been happily said, the general truth may be stated, that nerve-matter is specialized into two kinds, of which one, collected into masses, has mainly the function of giving out molecular motion, though it still can to some extent conduct it; while the other, collected together in threads, has mainly the function of conducting molecular motion. Hence results a generalized idea of nervous functions, which, to again avail myself of Mr. Herbert Spencer's expressive terms, are divisible into *recipio-motor*, *libero-motor*, and *dirigo-motor*. Each afferent nerve is a recipio-motor agent, each efferent nerve is a dirigo-motor agent, whilst the nervous centres are composed of libero-motor elements along with elements which perform both the other functions.

But though the gray and white substances have in a general way distinct properties and duties, it would seem as if the differentiation was not absolute, and that the former shared the conducting properties of the latter. It has even been claimed that the gray substance is essentially the channel through which sensory impressions are conducted upwards; for if all the white columns of the cord are completely divided, but the gray core is uninjured, the sensibility of the parts below the section continues perfect or nearly so; whilst, however carefully the white columns are preserved from damage, if the gray substance be divided sensibility is almost totally abolished. Dr. Lockhart Clarke has shown that the larger portion of the posterior nerve-fibres cross the columns and enter the gray substance, and, passing up, cease to be distinctly traced; others pass through the gray substance, and, returning to the columns, pass upwards. And it is not improbable that these carry up the impressions received from peripheral impact.*

Among the notes left by John Hunter there is a record of a case of paraplegia, in which it is stated that when the patient was asked whether *he felt* the irritation by which the motions of his legs were excited, he replied, glancing at his limbs,—"No, sir; but you see *my legs* do." This will remind you of a conditioned physiological autonomy of the spinal cord, which is declared by certain automatic reflex phenomena. This endowment of the cord as an independent nerve-centre often becomes in the Palsies manifest to an extraordinary degree, an increased tendency to reflex movements being exhibited when the control of the brain is totally annihilated. And we shall see, too, in such cases that, as voluntary power is gradually regained, the susceptibility to involuntary movements will lessen both in extent and force. This diagram (Fig. 8) shows the ordinary course of a sensory impression going to the brain by the simplest and most direct route; but when there is a fault in the route, then the purely reflex action of the cord is exhibited, and the impression is transmitted by inter-communication.

The ordinary course of a sensory impression to the brain is through the ganglion-cell, *a*, and the commissural fibre, *a*, which crosses to the opposite half of the cord. In the event of this being divided, the impression is transmitted through an intermediate ganglion-cell, *b*, to a group of motor cells in the anterior horn, *c*, and is then transmitted through motor nerve, M, to the muscles of the same side. If the impression be still stronger, the muscles of the opposite side are called

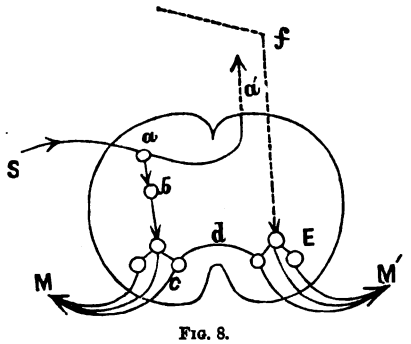

FIG. 8.

S. Sensory root. M. Motor root.

into reflex action through the communicating fibre, *d*. The group of motor cells may also be called into action by the voluntary nerve, *f*, which decussates at the lower part of the medulla oblongata.

Having called your attention to the importance of the full comprehension of this interesting subject in the exploration and appreciation of many of the disorders of the nervous system, I shall forego further details, except to refer briefly to several vital points in the laws formulated by Pflüger, and which have been confirmed by Schröder van der Kolk. 1. The reflection is unilateral; that is, it occurs on the same side as the impression when the induced reflex movements are limited to one side of the body. 2. But it may happen that the unilateral impression is not exhausted, and that it reaches secondarily the other half of the cord; in such a case the motor fibres consecutively excited always correspond to those which have received the first excitation, so that the group of muscles which contract, which secondarily contract, are the same as those on the side of the body primarily excited. 3. It may be that the determined reflex movements are of equal intensity on both sides; but if this is not the case, they are always strongest on the side to which the stimulus has been applied. 4. When the excito-motor influence does not extend beyond the disturbed sensory ganglion, or when in its irradiation from below upward it fails to reach the medulla oblongata, the reflex movements remain localized; but if it be propagated to the medulla oblongata the movements are generalized, for the medulla is the head-centre where the local inferior centres, concerned with nearly all the parts of the body, are brought into communication; it is the centre of irradiation of reflex movements, in order that all the muscles of the body may participate in such movements.

Before dismissing the subject I ought, however, to dwell for a moment on one other fundamental fact of function, whose practical bearing you will readily own when we come to consider the palsies individually. In 1840, Henle and Stilling showed that th muscular tissue of arteries responded in obedience to the impression conveyed to it by nerves, and according to its contraction and dilatation is a smaller or larger amount of blood allowed to pass. This office of the nervous system compels us to add, as an habitual element of its unit of composition in its completest form,—to the nervous arc, consisting of the afferent thread, the ganglion-corpuscle, and the issuing efferent thread, and the centripetal thread subordinating a lower and a higher centre,—a *vaso-motor* thread, an additional series of efferent nerves, running to that

* See A Lecture on some points in the Clinical History and Pathogeny of Locomotor Ataxy. By Meredith Clymer, M.D. MEDICAL RECORD, vol. iv., No. 28, 1870.

part of the body in which the two ends of the nervous arc lie, and which puts the blood-vessels in relation with the other portions of the apparatus. Exactly how this is done is in dispute, and to determine the relative share exercised by the sympathetic and the cerebro-spinal fibres in this duty is not a simple matter. I have no intention of discussing the problem of vaso-motor innervation, but I think the safest theory, the one most consistent with observed facts and with analogy, teaches the combined influences of the sympathetic and spinal fibres, each always liable to the influence of the other, there being actual functional antagonism between the two orders. This theory—that of moderator nerves, proposed in 1854 by Virchow—may be briefly stated: The blood-vessels receive two classes of nerves,—one belonging to the sympathetic, and the other to the cerebro-spinal, system. The office of the sympathetic fibres is to cause contraction of the vessels, whilst that of the cerebro-spinal fibres is to cause their dilatation. In a state of health these influences are compensatory and mutually moderating, and the result is vascular tonus. Should the spinal vaso-motors become abnormally excited, then their action is predominant, and the consequence is dilatation of the blood-vessels and increased body-heat. The same effect would happen were the sympathetic vaso-motory fibres paralyzed. If, on the contrary, the spinal fibres, the dilators, are disabled, then the sympathetic constrictors, freed from all restraint, will cause contraction of the vessels and a fall of temperature.

The general and local circulation is then regulated for its special needs by means of the influence exercised by the vaso-motor nerves on the blood-vessels. The peripheral circulation and the local body-heat present some curious phenomena in the palsies, which will be described in their proper places. I may, however, make here brief mention of the interesting observations of Dr. Lepine, of Paris, regarding the relative thermic variations in the sound and paralyzed limbs of persons suffering from unilateral palsy. He found that, when he placed the limbs of both sides under precisely similar conditions, noteworthy differences in their relative temperature happened. For example, when both limbs are rapidly cooled to the same degree in cases of recent hemiplegia, the affected limb, which should be the warmer one, will suffer a more rapid and greater fall of temperature. But if this reduction be carried beyond a certain point, then the relation is again disturbed, and the sound limbs lose most heat. In old hemiplegias, where the affected limb is the colder, this becomes relatively warmer to the sound one, when both are exposed to a low temperature. When both limbs are artificially warmed, the palsied limb will remain the colder as a general rule. Hence it would seem that the fluctuations of temperature in a limb whose vaso-motors are paralyzed are not so great as those in a sound limb where they are functionally whole. A possible explanation of these phenomena may be given by admitting that the action of the vaso-motor nerves, necessary for the sudden adaptation of the temperature to the surrounding media, takes place more slowly and less completely on the palsied side.

Some persons seem to possess a certain volitional power over the action of the vaso-motor nerves, by means of which they can, within given limits, influence the state of the peripheral circulation. A travelling mountebank exhibited a wonderful control over the hue of his face, becoming flushed or deadly pale as he pleased. I have now under observation a gentleman who, for seventeen years, has been able to produce at will contraction and roughness of the skin, with prominence of the papillæ, and erection of the hairs—cutis-anserina, or goose-flesh—with apparent loss of heat, and visible paleness of the surface. He says that after the volitional act a peculiar feeling seems to start from the upper cervical region, attended by a sensation at the præcordial region like that of sudden fear. In this case there must be a double influence exercised both on the nerve-fibres going to the organic muscular tissue in the interspaces between the basis of the papillæ of the cutis, and the vaso-motors.

Whatever autonomy the several nervous centres may possess and show in the various acts of organic life, when they come to take part in those functions which put man, made up of component fractions, into relation with himself as a whole, and with the external world, we find a mutual interdependence, a necessary blending and sharing of duties, which cannot be dissociated without causing a jangle in the working of the machine, expressed by functional troubles. The perfect sensory-motor cycle may be represented by two currents in opposite directions, separated by organs of reception and production. These currents or transmissions are, as we have seen, through the white substance, the incoming and outgoing fibres, the gray substance being the centres where reception and production have their seat. By these constituents molecular motion is given out and molecular motion is conveyed, and this naturally involves disintegration and reintegration—perpetual waste and renewal; and we shall see that some of the forms of the class of disorders that is going to occupy us would seem an outcome from this loss of balance between expenditure and production, and hence the ensuing disturbances may be styled qualitative and not quantitative, for they cannot be detected by the senses, even when aided by the acutest lenses. Besides, all the senses may for the time be shut by some fault in that impalpable act—nutrition; or by a flaw in the wholesome blood; or by some leperous distilment through the veins. All these may hinder function and yet leave no sign.

PHILADELPHIA STATISTICS.—From a "Report on Meteorology and Epidemics," by W. L. Wells, M.D., of Philadelphia (*Am. Jour. Med. Sciences*), the subjoined items are extracted: In 1869 there were reported at the Board of Health in Philadelphia 14,786 deaths. Taking the population at 800,000, this makes one death in 54, or 1.84 per cent. of the total population. The deaths among males amounted to 7,644; among females to 7,142. In 1869 there were 457 stillborn males, and only 332 stillborn females.

A NEW FEVER DISCOVERED.—Dr. J. C. Faget, of New Orleans, La., claims to have discovered a new kind of fever, which he designates as "Malarial Catarrhal Hemorrhagic Fever." This physician does not believe that creoles have yellow fever.—*N. O. Jour. of Medicine.*

COMMUNICATION BETWEEN THE HEPATIC DUCTS AND LYMPHATICS.—According to H. D. Schmidt, M.D., of New Orleans (*The N. O. Jour. of Med.*), Mr. Natilis Guillot is the only author who has asserted the existence of a natural communication between the hepatic ducts and lymphatics.

AUSTRIAN LIBERALITY.—The University of Vienna has decided to open its medical lectures and confer medical diplomas on women.

VACCINATION IN PARIS.—Two thousand persons went to one of the *mairies* in Paris for vaccination from the heifer in one morning last month.

Original Communications.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

Article I.

PRELIMINARY—GENERAL PRINCIPLES, HYPOTHESES AND CONCLUSIONS—THREE SORTS OF SYMMETRY—MODIFICATION OF THE ARCHETYPE.

The attempt will be made in these articles to determine, as nearly as is possible in the present state of our knowledge, the corresponding muscles of the fore and hind limbs of man, and to identify them with each other upon an hypothesis of antero-posterior symmetry—this involving consideration of the operation of vital force as analogous to that of polar force, and of the result of the *nisus formativus* as ideally identical with that of polarity.* In this light, muscles of fore and hind extremities (as will appear in the sequel) are not 'homologous' in the general acceptation of that term; nor even 'serial homologues' in Owen's definition of that expression, which implies a different idea, viz.—similar parallel repetition instead of opposite reversed repetition and true symmetrical antagonism. This last is known, for either of the three possible poles of the body, as 'antitypy;' and for the poles of the longitudinal axis in particular, as 'longitypy.'

Says the most accomplished, as well as the most distinguished, anatomist † of this country—

"* * * if antero-posterior symmetry can be shown to exist in the bones, then we can feel some confidence, that whatever the difficulties at present may be with regard to the muscles, nerves, and vessels, they will sooner or later be overcome."—Convinced that it has been proven in respect of the bones—and largely by the labors of him who has just spoken—we indulge the hope of tracing it some way at least among the muscles. However we may grope in the dark—however we may fail to touch that truth which will ultimately be determined—surely any advance in the right direction is better than a stand-still; and even errors, when discovered, will become light-ships to warn others off the shoals on which we foundered.

For the basis of most studies in what is called, with a shade of derision, 'transcendental ‡ anatomy,' doubtless we are mainly indebted to Owen's elaboration, with surprising skill, care, and precision, of Carus' idea of a vertebrate archetype. Some of the determinations that will be made, rest upon the assumption, that Owen's theory of the vertebrate endo-skeleton is in the main correct. But this illustrious man did not adopt the idea of fore and hind symmetry; his 'homotypy' or 'serial homology' is not exactly what is meant by 'antitypy;' and it is in provision for the latter that his archetype is to be remodelled in one feature (see below). Wyman has indicated (*l. c.* p. 278) the required modification. To his important paper I am deeply indebted, both for a clearer understanding of the principles that I believe to underlie the whole subject, and for special determinations of antitypic bones upon which identification of particular muscles rests. Wilder * has investigated in the light of polarity with special reference to the muscles. To him I am also under obligations (particularly for ideas advanced regarding 'long,' 'short' etc., muscles), although I cannot endorse all of his identifications. Except to these authors, I have no acknowledgments to make, the determinations of muscles, whether coinciding or conflicting with the views of others, being in every instance the result of independent study. Meckel, Duvernoy, and other distinguished anatomists who have handled the muscular homologies, have done so from a different standpoint; and I have refrained from study of their work in this special field, believing that however much might thereby have been gained in some respects, it would have been more than counterbalanced by the unconscious bias of judgment that would have ensued; and preferring to take larger risk of going astray through want of some information that might have been obtained, in order that I might work up the subject anew.

In the present article are considered some of the general principles involved in the idea of longitudinal symmetry, as an hypothesis necessary for the recognition of the existence of muscular correlatives in the two limbs. In the next, the osseous basis of the muscular correspondences will be laid down; when we shall be prepared to take up the muscles in detail. I must presume throughout upon the reader's familiarity with the tools of thought peculiar to this department of knowledge, and with the notion of the vertebrate archetype: for to stop to explain either would be to swell the papers beyond reasonable limits.

The Vertebrate is the highest one of four types or plans upon which all animal organisms † are held to be constructed; the others are, descending in the scale, the Annulate, Saccate, and Radiate. The last named is typified by the *star;* organs are peripheral around one central axis or dynamic point, with no preponderance toward one pole; like a sphere, involving all dimensions, expressing none; its essence is called 'radiality,' for the morphologically identical, if teleologically diverse sphæromeres, radiate like wheel-spokes. The molluscous or saccate is typified by the *sac*, in which viscera are enclosed; principal nervous ganglia about the œsophagus; heart on outside of flexed intestine (*fide* Morse); its essence is called 'laterality;' development tends sideways, or to the poles of the transverse horizontal axis. The annulate or articulate is typified by the *ring*, of which there is a conjoined series, each segment holding a section of the digestive system between one of the nervous, ventrad, and of the vascular, dorsad; an arrangement modified at one end by encircling of œsophagus with a neural ring (*fide* Allen): its essence is held to be 'tergality' or 'verticality;' weight of organization tending to the poles of the transverse vertical axis. The vertebrate is typified by the *double-ring* (*sc.* 'a vertebra'); it is a succession of morphologically identical figures-of-8, forming a segmented series. In the single-ringed animal the embryo develops from the ventral aspect of the ovum; in the double-ringed, from the dorsal; in the latter, there is a notochord ‡; the neural axis, instead of being ventrad,

* Faraday's definition of polarity:—"An axis of power, having contrary forces exactly equal in opposite directions."

† Jeffries Wyman, "*On Symmetry and Homology in Limbs;*" Proc. Bost. Soc. Nat. Hist., June, 1867, p. 277.

‡ The word may be accepted as expressing the transcendent importance of the investigations that alone can bring order out of a chaotic mass of observed facts, and make a philosophy of anatomy possible.

* Burt G. Wilder, S. B., "*On Morphology and Teleology, especially in the Limbs of Mammalia.*" Mem. Bost. Soc. Nat. Hist., I. (Nov. 1865.)

† Except *Protozoa*, in which great group plans have not been satisfactorily determined.

‡ Yet, Kupffer's researches, corroborating Kowalersky's, regarding embryology of the invertebrate *Phallusia*, show certain vertebrate conditions. He confirms the existence of a notochord. "At this stage one could not imagine a more beautiful model of a vertebrate embryo, with the neural tube on one side of the axis, and a visceral tube on the other."—*Nature*, p. —. London, 1869.

or encircling any part of the alimentary tract, is dorsad, and fills the upper loop of the vertebra; the lower ring receives alimentary and circulatory apparatus (and special nerves). The essence of this plan is called 'longitudinality;' it is preponderance of organization along the longitudinal horizontal axis; or 'cephality'—actual exaltation both of organization and function at one of the poles of this axis; although theoretically the tendency of development is the same at either pole.

Thus each one of the three higher types appropriates to itself more particularly one of the three only possible perpendicular axes of extension of a solid. We cannot conceive of organisms taking special axes of development without conception of some sort of *symmetry* as the result of unfolding a plan of organization. Yet not absolutely perfect symmetry, which probably does not exist in nature, any more than does that abstraction called 'a straight line.' Crystallographers deny it, even; much less, then, is it to be expected when the perfect operation of polar force in distribution of matter is disturbed by overruling, adaptive life-force, the main office of which, morphologically speaking, is the modifying and diversifying of general means for special ends. Only the underlying idea, so to speak, is one of symmetry. Confining attention now to the double-ring plan, we have first to observe how it is obscured by cephalization, and then to discover what indications of what kinds of symmetry we may.

'Vertebral' means simply 'flexible;' but now we have the word for the fact that an organism so moulded, is composed of a succession of segments. These are held to be 'ideally' identical, and to be laid over against each other in the long axis of the body, by a sort of 'vegetative repetition,' until the requirements of an animal's eidolon are fulfilled. But here cephalization operates to make the animal what it is actually to become, by modifying simple superimposition of similar segments, and so obscuring the original idea. In diversifying segments, it masks them. At one end of the body, an individual double-ring expands and is distorted, for example, into a pair of parietals, parts of the sphenoid and temporal 'bones,' and the os hyoides; at the other, it shrinks into a stunted os coccygis; these are extremes of exaltation and degradation of development. A caudal vertebra is sometimes not so much like a dorsal, for instance, as it is like a phalangeal internode. In some longicaudate mammals, in which the neural canal is not continued through the caudal series of vertebræ,—in which zygapophyses and other processes disappear—these bones are not vertebræ at all to the physical eye; neither is the coccygeal 'vomer' of birds. They may be called *larval;* but not the less on this account are they vertebræ. None deny this. So, then, in the cranium, where—to continue the simile—the vertebræ are become neural *imagines;* not the less on this account are they true vertebræ. Disconnection of some of the parts of a vertebra, and their fusion with another, is allowed by none to weigh against considering such bone in its true light; *e. g.*, the atlas is certainly a vertebra, though it has only articulating surfaces in place of true zygapophyses, no hæmapophyses, and nothing but a hypapophysis instead of a centrum that takes shape and place as the 'odontoid process of the axis.' Similarly, the occipital segment is no less a vertebra, because its shape is further modified, and one half of it (the lower ring-hæmal arch) is carried away from the other (centrum and neural arch), and rests upon the thorax in the shape of 'scapular arch,' from which hangs an 'appendage' (*vuly.* "arm"). A dorsal vertebra is not only the 'bone' so named by anthropotomists, but includes its pair of pleurapophyses, pair of hæmapophyses (together=a pair of ribs), and its hæmal spine (=corresponding segment of sternum). In reasoning on these matters, the physical eye must sometimes be closed to give the mind's fair play; we treat of things *in posse* as well as *in esse;* we argue *de jure* as well as *de facto;* we dismiss the concrete for the abstract; or rather, we search for what of the latter must lie enwombed in the former. It must be evident without further illustration, that *shape*—mere moulding of contour of parts—goes for little or nothing; and that a vertebra is simply one individual transverse segment of a longitudinally segmented, double-barrelled body.

From another point of view, certain anthropotomical distinctions are seen to be wholly arbitrary. Running through the vertebrate series, 'neck,' 'chest,' 'sacrum,' etc., dissolve in each other. In the fish with pectoral limb attached to the occiput, how many vertebræ are 'cervical'? In the snake with "innumerable ribs" how many are 'thoracic'? How many compose a whale's 'sacrum,' the very position of which can only be surmised by the rudimentary pelvic bones suspended beneath? Location in the series, like shape, is no guide. We only gain safe resting-place in holding vertebræ to be morphologically identical—distant as this standpoint certainly is, numerous and slippery as seem to be the stepping-stones by which we reach it.

A kind of symmetry exists between the two halves of the Vertebrate, let it be divided in the plane of any two of its three possible perpendicular axes of extension. The first of these is so palpable as to require little more than mention. The second is obscure, and only traceable in few instances; ordinarily it has no actual existence. The third is the one we purpose to discuss more particularly.

"Right" and "left" express the first kind—*bilateral* symmetry; usually preserved so nearly inviolate, that exceptions to the fact that one side of the body repeats the other are justly regarded as anomalies. It holds with all the framework of the body, and its clothing, as well as with the principal neural tracts and organs of the special senses; though not with the main viscera of the (adult) thorax and abdomen. This, it will be observed, is not 'serial' repetition sideways; the body is either ambidextrous or ambisinistrous, not sinistro-dextrous; it is opposed as well as apposed repetition; it is transverse polar antagonism, and therefore symmetrical repetition. This sort of symmetry, if not preserved with mathematical exactitude, is nevertheless unequivocal and unquestionable. Furthermore:—"All organs which are thus unlike or unsymmetrical in the adult, have been shown by embryologists * * to be alike in the embryo; the deviations from true symmetry taking place as development advances. * * The organs of the great cavities in adult vertebrates are almost uniformly unsymmetrical; nevertheless, in the embryo the symmetry of these parts, even of the liver, is complete." *

If a plane be passed longitudinally, as before, but horizontally † instead of vertically, the body is divided into dorsal and ventral halves, in which we are to look for *supero-inferior* or 'dorsabdominal' symmetry. Since each loop of the double ring ideally repeats the

* WYMAN, *l. c.*, p. 247.—Among notable examples of bilateral asymmetry, this author adduces the unequal nostrils and bent vomer of some cetaceans; the left tusk of the narwhale and mastodon; and especially the very distorted flat-fishes. To these I may add that singular limicoline bird, the *Anarhynchus*, in which the beak is bent upward and *to one side.*

† Man's morphological position is horizontal, like any other animal's; expressions of *direction* in these papers hold this in view.

other, such symmetry may theoretically be said to exist; but it is rarely found. The plane just supposed passes through the chain of conjoined vertebral centra; above it, lies the neural, and below it, the hæmal, series of arches or rings. At no point in the series do these give anything like actual reversed repetitions of each other. In the head, *e. g.*, neurapophyses and neural spines are enormously expanded for accommodation of the great nervous masses they contain. Further backward, the neural canal shrinks, and the hæmal swells with its great pleurapophyses to protect the viscera: further back still, the nerve-tube may close, the myelon end, and only centra and hæmal arches be continued further. Thus the cross-point of the figure-of-8 continually wavers; it may rise till 8 becomes 0, or sink until nearly the same result is produced. Yet there are instances of true supero-inferior symmetry, as in the tail of the homocercal fish, which, horizontally bisected, gives upper and lower halves that are reversed copies of each other.

The rigid adherence to, and clear expression of, bilateral symmetry, or 'lateritypy,' unquestionably results from the essentially similar functions of the two sides of the body—the nearly identical uses to which they are put; for teleology is the master of morphology—is the end and aim of all morphology. Departure from supero-inferior symmetry represents the converse of the same theorem: for no organs can be more diverse in function than those contained, respectively, in the neural and hæmal arches.

Intermediate between these two, both as to its causes and as to their effects, lies the expression of that *antero-posterior* symmetry which we can confidently determine: it is not so evident as the first kind: it is far more so than the second kind. It is more evident in the limbs than in the trunk. In the trunk, cephalization masks it under such guise, that its few apostles number comparatively fewer disciples, and both have been often reviled. In the limbs, it seems to be hidden precisely in the ratio of the differentiation of function in —the teleological discrepancy between—the fore and hind members. Thus it is more evident in quadrupeds (especially in some natatorial and scansorial ones) that use the four limbs nearly in the same way, than in bipeds, as man and birds, the anterior extremities of which are highly specialized. But however distorted and disguised, it may always be discerned, and traced out with greater or lesser detail. While this is true even of the adult, "in the early embryo," says Wyman (*l. c.* p. 248), "the fore and hind limbs, however widely they may differ in the adult, are as nearly alike * * as are corresponding limbs of the right and left sides."

It is not to be inferred from what has been said, that head and pelvis 'repeat' each other; though such is the bold language of Oken's anatomical parable. We are not to assume that, *e.g.*, the os mentis is repeated in the os pubis: for the antitype of the latter is found, if anywhere, in the bow made at the top of the thorax by the clavicle or coracoid, or both. Knowing the number of vertebræ in the head, it is difficult or impossible to homologize the four with caudal segments that range from less than six to as many as thirty: or with sacral segments, which also vary within wide limits. Nor is it necessary, here at any rate, to go into those speculations, strenuously advocated by some, that have regard to the mutually repetitive relations of the oral and anal outlets of the alimentary canal or of the respiratory and genito-urinary openings.* Confining attention to the neural axis, certain well-known facts in respect of its development may be cited. Its growth is not serial, in one direction from one point, but symmetrical or nearly so, for a time, from a central neutral point in opposite directions, with corresponding dilatations at the two ends.* In like manner, ossification of vertebral segments begins at an intermediate point in the series, and proceeds in both directions towards the two extremities. (Consult also in this connection the investigations of the author just cited, regarding development of the limbs—to which we shall have subsequent occasion to allude.)

In face of even the foregoing paragraphs, in which little more than mention is made of some of the arguments that favor the view we desire to support, it would be irrational to ignore—still more so to deny—the existence of antero-posterior symmetry as an underlying principle of organization, the force of which is felt in every part of the body, and traces of the force of which may be everywhere discerned with more or less clearness. It only remains to indicate the modification of the archetype required for its recognition.

No one of Owen's† three "relations of homology" includes that longitudinal antitypy which is implied in the idea of polar symmetry. His "general" homology defines the place of a part in its own vertebral segment —determines what element of a vertebra it is; *e. g.*, basisphenoid to be centrum of the mesencephalic segment. By "special" homology he finds the same part in different animals; e. g., determines it to be the third metatarsal and corresponding phalanges that chiefly form a solidungulate foot. By "serial" homology he denotes that a part repeats in its own vertebra the corresponding part of another; *e. g.*, that the 'styloid process of the temporal' is to the mesencephalic vertebra what the osseous part of a rib is to a dorsal. To the last kind of homology he applies the special name of "homotypy." This comes nearest to what we are now discussing, but is not the same, for

* Interesting as such an inquiry would be, and considerable as are the arguments in favor of such a view. For example:—"In the embryo of all air-breathing animals, there is developed from the abdominal side of each end of the straight intestine a sac; that in front forming the lung, and that behind the allantois, and each opening into the intestine by a narrow neck. * * The correspondence between the two ends is still further, but less clearly, indicated in the subsequent division of them, the fore end into mouth and nostrils, or respiratory and digestive portions, and the hind end into anal and genito-urinary portions, and still further by the development of the tongue on the floor of the mouth, and the male organ on that of the genital portion of the intestine. In most mammals, the genito-urinary portion becomes wholly separated from the digestive, while the respiratory does not. Nevertheless, in the embryo, the first retains its connection for a certain time, as is permanently the case in birds and reptiles."—(WYMAN, *l. c.*, p. 251.)

In support of an hypothesis of fore and hind symmetry, we are not obliged to presume that the same or even corresponding *organs*, actual or potential, must be found at the poles of the trunk. That the same elements of the framework at least should be found, is as indispensable as it is true that they have been proven to exist. But that special organs may be introduced for special ends is indubitable; nor are these necessarily even "modified representatives" of each other. The matter is capable of, and has received, less heroic treatment, as well as sounder explanation: as will be seen by referring to that portion of Prof. Wyman's article headed "*Analogy between symmetry and polarity.*" (p. 254). It is there shown, that matter free to act under magnetic influence, and capable of polarity, is distributed in a manner that "corresponds, first, to all that we designate as right and left in normal development; second, to all that we designate as fore and hind with reference to the long axis of the body, and which is characterized by symmetry in structure."

* "In some adult fishes the spinal marrow ends in a ganglionic enlargement, forming a kind of caudal brain."—(WYMAN, *l. c.*, p.—)

In Hexapodous insects, certain spiders (*Hersilia*), and most Myriapods, antero-posterior symmetry is very plainly marked. Thus in the cockroach (*Blatta*) the jointed caudal filaments exactly repeat in form and structure the antennæ, even to development of special sense organs. On examining specimens treated with liquor potassæ I have found sense organs (probably those of smell) consisting of minute pits like those found in the antennæ, except that they are larger and more numerous. Dr. Anton Dohrn has recently discovered sense-organs in the caudal appendages of the mole cricket (*Gryllotalpa*). Certain other Orthopetra (*Mantis* especially) and Neuroptera, have remarkably antenniform caudal appendages. In the Myriapods antero-posterior symmetry is remarkable; the limbs of the anterior half of the body pointing headwards, those of the posterior half being directed tailwards, while the last pair of legs are, as in the Centipeds, specially developed into antennæ-like organs.—A. S. PACKARD, JR., in "*Guide to the Study of Insects*," and "*American Naturalist*," passim.

† OWEN, *Report on the Homologies of the Vertebrate Skeleton.*

there is no recognition of the *reversed* repetition that is the essential idea of symmetry. Right and left hands, *e. g.*, are symmetrical, precisely because they are not transverse 'serial' homologues: bilateral symmetry gives reversed copies of parts. Parity of reasoning demands that, if the notion of fore and hind symmetry be entertained, vertebral segments must not be conceived as 'serial' homologues—as continuously following after each other; but as reversely repeating each other on either side of, in either direction from, a certain median neutral point. Arrows illustrating this idea point <—— ——>; not ——> ——>, as implied in Owen's archetype.

A vertical transverse plane passes somewhere* across the linked chain called a 'vertebrate,' dividing it into two series of segments, that ideally repeat and represent each other symmetrically: the first one behind the plane the first one in front of the plane, and so on. This hypothesis ignores any specialization of one end of the archetype, and presupposes the modification that has been indicated. It is as if corresponding halves of two animals were joined end to end: the archetype is dicephalic or dicercal—not cephalo-cercal.

These views are strongly supported, if not demonstrated to be true, by both the development and the adult condition of the limbs, as we hope to show in another paper; when the fore and hind members will be considered as longitypes, precisely in the sense that right and left ones are laterityps.

COMPARATIVE VALUE OF THE GALVANIC AND FARADIC CURRENTS.

By A. D. ROCKWELL, M.D.,

OF NEW YORK.

Since the time of Remak, the comparative value of the galvanic and faradic currents in therapeutics has excited continual interest, and at one time was the subject of angry controversy. At the present day all electro-therapeutists who keep abreast of the progress of their department agree that both currents are of service; that one will fulfil certain conditions for which the other is inadequate, and that no one who expects to secure in practice the complete effects of electrization can dispense with either. Concerning the special indications for the use of one or the other, opinions widely and honestly differ, according to the opportunities and experience of each individual. In Germany, where the school of Remak is dominant, the galvanic is used more than the faradic; in France, at least among the disciples of Duchenne, the faradic more than the galvanic. In England and America both currents are employed, general practitioners using chiefly the faradic, while specialists use both with more or less exclusiveness.

Much of the confusion that exists concerning the differential indications for the use of the galvanic or faradic currents arises from an imperfect or erroneous or exaggerated conception of the distinctions in their physiological effects.

The general belief or supposition is that there is between them a radical and important difference in *kind*, and that an appreciation of this distinction is essential for a knowledge of the differential indications for their use. From the accumulating results of experiment and experience in electro-physiology, diagnosis, and therapeutics, we think that there is strong reason for regarding the essential distinction in the effects of these currents on the body as mainly of *degree*, and that this is the scientific basis for their differential employment.

Thus the galvanic current applied on the face and head produces flashes before the retina, while, as a rule, the faradic will not. We have, however, frequently treated certain sensitive pathological conditions where the same flashes were caused by the faradic. With the improvement in the general condition of such patients, this unusual susceptibility to the faradic influence always disappears. An important peculiarity of the galvanic current is that, when applied on the neck, it causes a metallic taste, and yet we have on several occasions treated cases of constitutional neuralgia combined with excessive irritability, where the same effect was markedly and even unpleasantly produced by the faradic current, when applied above the seventh cervical vertebra. Other well-recognized peculiarities in the effects of the galvanic current, distinguishing it from those of the faradic, are *giddiness* and *vertigo*, when applied on or near the head, *diplegic contractions* and special sensations down the upper extremities and over the body, when applied to the cervical sympathetic; marked chemical effects, especially when used in large quantity, redness and burning sensations of the skin at the points on the surface where the electrodes are applied. All of these effects are observed in a less degree from the faradic current, and some of them in cases of great abnormal sensitiveness are very decided. When we come to study their therapeutic effects, we also find that both currents differ chiefly in degree. In the form of localized electrization, both can produce muscular contractions in paralyzed muscles and relieve local neuralgia; both cause absorption of abnormal secretions, and both can directly affect the brain, spinal cord, sympathetic, and all the internal organs, producing, in different degrees, the various therapeutic results that directly and indirectly flow from electrical excitation of these parts. In the form of general electrization both currents, besides producing most of the results of localized electrization, act as powerfully stimulating tonics, and thus form most efficient aids in the relief and cure of nervous exhaustion, nervous dyspepsia, constitutional neuralgia, and of a wide range of nervous diseases associated with or dependent on general debility.

In electro-surgery both currents avail to discuss tumors, heal ulcers, and hasten absorption, although the galvanic current, when used in large quantity, produces cauterizing effects to which the faradic is unequal. And yet the difference in *degree* between the effects of the two currents is so marked and so clearly demonstrable as to be practically equivalent in certain instances to a difference in *kind*, and to give very important and remarkable advantages to one current or the other, according to the indications offered.

ADVANTAGES OF THE GALVANIC OVER THE FARADIC CURRENT.

The advantages of the galvanic over the faradic current are:—

1st. *A greater power of overcoming resistance.*

It therefore affects the brain, spinal cord, and sympathetic more powerfully than the faradic, since the anatomical position of these parts is such that considerable resistance must be overcome in order to directly affect them.

For the same reason it is usually to be preferred when it is desired to affect the middle and internal ear, the retina, and the muscles of the eye.

2d. *A power of producing muscular contractions in cases where the faradic fails.*

* Through the middle, *i. e.*, neutral point of the longitudinal axis; precise position not determinable, and probably varying with different, though fixed for the same, species.

This peculiarity of the galvanic current has been observed so frequently, and in such striking instances, that it has become an accepted fact of electro-therapeutical science.

After a certain amount of treatment by the galvanic current, the paralyzed muscles frequently resume their susceptibility to the faradic.

3d. *A different and far more potent chemical action.*

The chemical power of the galvanic current is most markedly seen when used for the purpose of galvano-cautery, or "galvano-caustic chemique."

In order to produce the energetic caustic effects of the galvanic current, it is necessary to use elements that generate quantity of electricity, and to combine them in such a way that the quantity produced shall be very large, since an ordinary single element, or indeed a large number of elements arranged for intensity, exhibit only a comparatively feeble cauterizing effect. It is because the galvanic current can be thus arranged for quantity, more than in any difference in kind between the effects of the two currents, that it has so marked and peculiar a superiority to the faradic as to practically amount to a difference in kind. The quantity of the faradic can be but slightly increased, and hence, although it does possess some chemical virtues and produces slight chemical effects, it is not indicated where such effects must be very energetic or concentrated. The superior efficacy of the galvanic current to the faradic, so often observed in the treatment of neuralgia, of atrophied muscles, rheumatism, &c., is probably due to its greater chemical or catalytic action. It probably induces more rapid and more important molecular and other changes in the tissues.

ADVANTAGES OF THE FARADIC OVER THE GALVANIC CURRENT.

The advantages of the faradic over the galvanic current are these :—

1*st. By virtue of its frequent interruptions it more easily produces muscular contractions when passed over the muscles or the nerves that supply them.*

In order to produce muscular contractions with the galvanic current, it is necessary to interrupt the current, and, unless it is quite powerful, to localize at least one of the electrodes over the motor nerve by which the muscle is supplied. On the contrary, the faradic current is in a condition of rapid interruptions, and produces contractions when indifferently passed over the surface of the muscle, as well as when localized on the main motor nerve that supplies it. This advantage of the faradic current is best appreciated in *general electrization*, the powerful tonic effects of which are partly and quite largely due to the passive exercise, and consequent important changes of tissue that result from the several thousand muscular contractions that take place during an ordinary sitting. In localized electrization this advantage is not so clearly or strongly marked, since in this method, by a proper knowledge of electro-therapeutical anatomy and sufficient care, it is possible to direct one of the electrodes on the motor points; and yet even here the faradic current is much more convenient, because its employment requires no arrangement for interruptions and less minuteness of attention to the situation of the "motor points." The exceptional cases of paralysis, where the muscles have lost their susceptibility to the faradic current, do not interfere with the general rule.

2*d. It is less likely to produce unpleasant or harmful effects than the galvanic.*

In certain acute and chronic pathological conditions, where it is desirable to produce a decidedly stimulating effect without marked catalytic action, the faradic current can alone be used with benefit and safety. To confirm this statement, we rest mainly on the evident results of clinical observation. We recall at least two cases of severe neuralgia of the trigeminus, where a mild and rapidly interrupted faradic current, applied on several occasions, relieved the pain very decidedly.

In order to hasten recovery, the constant current from but four of Bunsen's cells was for a moment directed along the course of the painful nerve. In both instances the neuralgia immediately returned with increased severity, but was relieved a second time, and soon recovered under the influence of the current first named. We may indeed refer to a number of cases of severe constitutional neuralgia and excessive nervous exhaustion where the faradic current invariably relieved, and where the galvanic as invariably aggravated the symptoms.

Our own experience teaches, that wherever the constant current can be used without injury, there also will a faradic current of relative intensity be harmless. It teaches further, as above stated, that in certain conditions where the faradic current is not only harmless, but of decided benefit, the galvanic, even when its tension is very slight, may occasion evil results.

FIG. 1.

GALVANIZATION OF THE SYMPATHETIC.

One of the most important advantages possessed by the galvanic over the faradic current is the readiness with which the former affects the sympathetic.

The attention of the profession was first called to this fact by Remak, who observed the occurrence of diplegic contractions when the superior cervical sympathetic was submitted to the influence of the constant current.

This observation of Remak was confirmed by Fieber, who produced similar phenomena in the living animal by exposing the sympathetic and directly galvanizing it.

It does not come within the scope of this short paper to theorize at length concerning the beneficial results following galvanization of the sympathetic.

In those cases of paralysis of vaso-motor nerves and arterial spasm that are benefited by this method of treatment, the favorable results may be ascribed in brief to the influence exerted on the vaso-motor nerves.

The few following cases may serve to illustrate some points in the above remarks :—

CASE OF PERSISTENT AND EXCESSIVE NAUSEA—RECOVERY FOLLOWS GALVANIZATION OF THE SYMPATHETIC.

Mr. H. S., a tall spare man, aged 49, was the victim of a mild form of nervous dyspepsia, from which he had suffered slightly for many years. Some three years since, a very annoying symptom supervened. Every morning soon after breakfast he observed a feeling of nausea that lasted a short time and then passed away.

This symptom gradually increased in severity and duration, until it became most distressing, and for more than two years no form of medication had afforded more than temporary relief. We first made use of the faradic current by the method of general electrization, directing the applications more especially to the back of the neck, so as to affect, as far as possible, the sympathetic. As no relief followed, we resorted to the galvanic current, applying (as illustrated in the cut) the positive pole at the inner border of the sternocleido-mastoideus muscle and the negative at the sixth cervical vertebra, and allowed a mild uninterrupted current to pass for three minutes. By this method the sympathetic was decidedly influenced, and relief was afforded. Succeeding applications gradually reduced the intensity of the nausea until the tenth séance, when it disappeared completely and has not since returned.

CASE OF DISORDERED NERVOUS ACTION RELIEVED BY GALVANIZATION OF THE SYMPATHETIC.

Mr. H., age 40, complained of an unpleasant feeling of constriction in the throat, and a constant pricking or tingling in the arms and hands. The patient, who was of a highly nervous organization, stated that these symptoms had existed for a number of years. During the last few months, however, they had become so decidedly aggravated as to excite alarm, and impelled him to seek professional advice.

FIG. 2.—General Electrization.*

* Fig 2 illustrates an application to the forehead, being the first step in the most thorough form of general electrization. For convenience of illustration the cut represents the patient as uncovered; in practice no such exposure is necessary.

A number of general applications with the faradic current were administered without special result. We then resolved to influence the sympathetic by the galvanic current.

The first application to either cervical sympathetic excited a decided perspiration in both axillæ and along the inner side of the arms. The symptoms of which he complained became rapidly less marked, and after twelve applications ceased to annoy him.

Patients suffering from cerebral effusions frequently speak of an unpleasant roughness in the eye. This symptom may probably be ascribed to dilatation of the smaller blood-vessels through weakness of the vaso-motor nerves. We have found that this condition is almost invariably relieved by galvanization of the cervical sympathetic.

AN AGGRAVATED CASE OF CHOREA RESISTS THE ACTION OF THE GALVANIC, BUT YIELDS TO GENERAL ELECTRIZATION WITH THE FARADIC CURRENT.

The little patient in whose case the results of treatment by the faradic current were so gratifying, was under the professional care of Dr. J. O. Farrington.

Dr. George T. Elliot was called in consultation, and by these gentlemen electricity was advised.

Some two months previous to the consultation certain abnormal movements—such as starting suddenly to his feet, throwing out a hand, or a foot, &c.—were observed by the teacher of the boy. Two weeks subsequently, the patient was seized with well-marked choreic symptoms of the right side of the body, and in two days the disturbance extended to the opposite side. So constant and violent were the movements of his arms and legs that it was impossible to keep him on a bed or sofa. It was necessary to place him on the carpet, surrounded by inflated rubber bags. Intelligence seemed to be perfect, but the power of speech was lost, and the sufferer made known his wants by impatient cries and ill-directed motions.

Sleep was impossible without the nightly administration of an opiate. Contrary to our judgment, but by suggestion, we commenced treatment by the use of a mild galvanic current directed especially to the base of the brain and the spinal tract; but this method served only to aggravate the child's condition. We then resorted to the faradic current by the method of general electrization (see Fig. 2), but so violent were the involuntary movements in the limbs and body of the patient, that it was with difficulty that he could be held in a sitting posture and his feet kept on the copper plate to which the negative pole was attached. The applications were *general*—every portion of the body, from the head to the feet, being influenced on each occasion.

Improvement was manifest from the very first. He was at once enabled to sleep soundly, although his opiate was reduced one-third, and after the fourth application it was dispensed with altogether. In the course of three weeks, during which time fifteen applications were given, the case was so far improved that the patient was able to utter distinctly words and sentences. The choreic symptoms were so much diminished that the boy could readily sit quiet and alone, and during an application was able to command the movements of his body and feet. Improvement continued during the administration of a few more applica-

tions, when the child was taken to the sea-shore, where in two weeks he quite recovered. Some three months since, after having enjoyed excellent health for a year and a half, the boy suffered from a second attack. He was immediately subjected to the influence of electrization, and recovered even more rapidly than before.

THE TREATMENT OF PHLEGMASIA DOLENS WITH OPIUM.

By C. C. P. CLARK, M.D.,

OSWEGO, N. Y.

Very few of the maladies of parturient women are more worthy of the attention of the obstetrician than phlegmasia dolens. This disease, it is true, is seldom the cause of death, but it is attended by very great suffering, and is often followed by very serious and protracted evils. The former feature is so eminent as to have given the disease its specific appellation: it is called, *par excellence*, "The Painful" Inflammation. The epithet is distinctive enough, for the complaint is actually attended by a greater amount of suffering than accompanies any other ordinary inflammation. It is not unusual for the patient to lie for many weeks in great and constant agony.

To this important element is to be added one of even greater seriousness in the ordinary sequelæ of the disease. These are long-continued and even permanent lameness and weakness of the affected limb, œdema and varicose veins, with the attendant evils of ulcers, eczematous affections, and depraved health.

These calamities are usually aggravated by each successive pregnancy and by casual derangements of the health, and are seldom entirely recovered from. The results of phlegmasia dolens thus cause many women literally to drag out for the rest of their lives a miserable existence.

Notwithstanding the serious character and the very considerable frequency of this disease, it has received very little attention in recent treatises on midwifery. Of the few authors within my reach it is not even mentioned in a large majority; Cazeaux and Bedford, for instance, among recent writers, have no account of it. When it is introduced, while its history and pathology are properly exhibited, the treatment that is prescribed is to me very unsatisfactory, and indeed very objectionable. Leeches, blisters, cathartics, diuretics, fomentations, and, in short, all the weapons by which inflammation is ever attacked, are prescribed with a promiscuousness that is characteristic of uncertainty and of (regular) quackery. A case published in the September number of the Journal of the Gynæcological Society of Boston, and republished in the Philadelphia Half-yearly Compendium of Medical Science, Part V., well illustrates the vagueness and the useless activity of this treatment. In that case, notwithstanding a sufficient variety of remedies, the disease, after running its course in the left lower extremity, attacked the right, and was sufficiently cured only after thirty-eight days to permit the patient "to sit up and walk about, some lameness and œdema still remaining." One hundred and sixteen days from the beginning of treatment "she uses her limbs freely, but they get tired easily and are often somewhat swollen at night."

This patient was treated by anodyne liniments, fomentations, sinapisms, poultices, laxatives, diuretics, hydrocyanic acid, quinine, carbonate of ammonia, chlorate of potash, hops, "et cet." The reporter concludes, as well he might after such treatment and such results, that "nature and time, with rest and an appropriate diet, are the most important elements in the cure."

I do not refer to this case because its treatment indicates any want of skill, for the medical gentleman who relates it is evidently a man of science and a close observer, but because it furnishes a fair representative of the common treatment of this disease to-day, and of the average results of that treatment.

For the last fifteen years I have treated this disease with a single remedy: that remedy is opium. Opium cures phlegmasia dolens with more certainty than quinine cures a tertian ague. I speak from the experience of more than a score of cases. The results have been uniform. The remedy does not simply make the patient comfortable: it cures the disease, if any remedy cures any disease. I never hesitate to assure a patient attacked with phlegmasia dolens that her sickness shall be short and painless, and shall not be followed by that disablement that the experience of some neighbor has taught her to fear.

The rule for the administration of the drug is simple: Let the pain be kept thoroughly subdued. It is not too late for the beneficial effect of the medicine so long as the disease is painful, but the sooner the treatment is begun the more complete is its remedial influence. In view of this fact, the first symptom of the disease should receive attention. That symptom is, I think, always pain in the lower part of the pelvis on one side. It may be near the groin, or the back, or the hip-joint, or it may be deeply and obscurely seated. It is generally not severe at first, but it is always accompanied by a certain hardness of the pulse that the *tactus eruditus* easily detects. But whether or not this preliminary pain be noticed, whether the suffering be extreme or moderate, whether the disease be accompanied by much or by little fever, whatever the state of the bowels, of the secretions, or of the excretions, the rule of treatment is the same: the pain must be met by opiates, which should be carried to the point of procuring absolute relief therefrom; and their use should be continued till it can be omitted without the recurrence of suffering.

That this remedy does not simply relieve pain, but also actually arrests the morbid process, will be obvious to any one who compares the course and duration of a case treated by it to the progress of one submitted to all or any part of the multifarious treatment that is laid down in the books. It will be still more obvious in the results of the disease; for, in a case early and thoroughly treated by opium, the femoral and other veins will be found after the sickness to be free from those fibrinous clots that under other treatment seal them up for ever. Even in cases where the morbid process has become mature and extensive before opium has been resorted to, the disease will not only be arrested by it, but the evil work already done will generally be undone. Existing fibrinous deposits will soften and dissolve into the current of the blood, and the affected veins will be left pervious. I know, as a matter of repeated and careful observation, that the signs of venous obstruction rarely or never show themselves in any considerable degree after a case of phlegmasia dolens that has been vigorously handled by opium.

The control of opium over active fibrinous inflammation of the veins is not confined to this seat of that disease. I have seen repeated instances of its power in those accidental cases of inflammation of the veins which intervene in the course of other diseases. I do not see in this any specific or peculiar power. I believe it is the same control which we see more or less evinced by opium over all the fibrinous inflammations. We all know the great influence that it displays, especially if used early, in peritonitis and pleuritis. It is not strange that it should check also an inflammation of

the veins. On the contrary, the seat and the other conditions of that inflammation are especially favorable to the influence and permission of the free use of opium. I may add that the parturient condition, anæmic, irritable, and exhausted, is especially suited to the beneficial effects of this drug.

I by no means claim originality in the use of this remedy in this disease. Most practitioners, I am well aware, resort to it for relieving pain and for procuring rest, and many of them, I have no doubt, place on it their main reliance. But I go farther than even these last: I use opium and nothing else,* and I make my patients comfortable and give them a quiet and complete cure.

Alcohol.—Anstie still appears as the great advocate of the use of alcohol. He thinks that in most, if not all constitutions, with the exception of those who live tranquil lives, free from anxiety, and with abundant opportunities for imbibing fresh air, and taking pleasant and healthful exercise, from one to one and a half ounces of absolute alcohol, in the shape of wine, beer, or spirits, is a valuable, if not indispensable article of diet; that in the febrile state, even with the red face and bounding pulse, from three to six, or even twelve times as much, may be required; that in debility not attended with fever there is no such tolerance, and alcohol then works very great mischief; that the recommendation of "plenty of port wine" to hysterical women is attended with results which are disastrous to the last degree; also in those two vast groups of neuroses, the neuralgic, and that which includes the thousand and one forms of hysteria and hypochondriasis. These patients also very readily develop a strong and dangerous liking for alcoholic beverages, which fever patients do not. There is a safe and healthy tolerance of alcohol in chronic debility induced by copious hemorrhages; also in phthisis in delicate persons, with a marked tendency to colliquative sweating, and inability to assimilate ordinary or fatty food; also in certain chronic neuralgias of the aged, when the power of digesting food is almost suspended; and in certain chronic infantile diseases, attended with marasmus and indigestion. In the whole series of the mental states which hover between hysteria and insanity, bromide of potash is far better than alcohol.—*Med. Press & Circular.*

Tapping of the Pericardium.—Dr. Löbel, of Vienna, states (in the *Central Blatt*, No. 3, 1870) that, to relieve dyspnœa in pericarditis, he removed some of the effused serum by a simple operation. To a glass syringe, capable of containing an ounce of fluid, a pointed canula-needle was adapted, as used for subcutaneous injections. A puncture was made in the third intercostal space, and the syringe soon filled, by suction, with a yellowish fluid. About three ounces of the latter were removed by three times repeating the same operation. Great relief was obtained, and the patient, with whom all other means had failed, was, after several days' sleeplessness, able to rest. The improvement did not last long, and hydrothorax soon supervened. The distress in about twelve days became again so great that some serum was removed in the same manner, the puncture being, however, made in the third intercostal space on the *right* side, the canula being directed to the left. Three ounces were again evacuated; but the patient, full sixty-eight years of age, died the next day. Hydrothorax was found on both sides, but the pericardium contained very little fluid. The holes made by the needle were very distinct; but no trace of blood, or lesion of the heart, could be discovered. Dr. Löbel thinks that this mode of procedure is very painless, but that the instrument to be used should, in future, be an improvement upon the syringe he employed.—*Lancet.*

* I shall not be understood as meaning that I might not give the patient a blue pill, or a dose of castor-oil or of spts. of nitre, as we do in all diseases where special circumstances require it.

Chloroform.—Dr. Simpson says that his recent case of death from chloroform was the first which has proved fatal in his practice. Death from asphyxia, or from syncope, may occur in some cases. Dr. Simpson says, death from asphyxia can generally be averted by at once arresting the inhalation of the drug whenever the breathing becomes noisy or stertorous. Death from syncope is far less under control, and has, apparently, been the cause of the majority of the fatal issues mentioned in the journals. Before the introduction of chloroform, patients sometimes died of syncope on the operating table. He gives many instances where slight operations, such as opening abscesses, have been followed by death before the introduction of chloroform. Hence, he argues, that probably the fatal terminations in some cases of chloroform are not *always* to be ascribed to the inhalation of the drug. At the various drug manufactories in Edinburgh, upwards of two millions of doses of chloroform are manufactured yearly. Dr. Simpson asks whether there is any other potent drug which could be administered with so few fatal results.—*Med. Press & Circular.*

The Discovery of the Animalcule Causing the Itch.—E. L. Keyes, M.D., N.Y. (*N. Y. Med. Journal*), in his very interesting report on Dermatology, assures us that the itch was known by the Chinese 4,000 years ago, and was called *tchong-kiai*, signifying pustules formed by a worm. As lately as the year 1821, Lugol offered 300 francs to any one who could show the animalcule causing the itch. This was finally done, first, in 1834, by François Renucci, assistant of Alibert, who extracted the insect in the presence of numerous spectators. Since that time the animalcule has been pretty generally considered to be the sole cause of the disease; but even now some authors deny to it the *rôle* of causality. Devergie, for example, arrives at these two conclusions:—1st. That the itch may be a spontaneous malady. 2d. That if the acarus is constantly present in the itch as a coincidence, yet the theory of its existence can just as well admit that the insect is a morbid product as that it is a morbid cause and agent of transmission.

Removal of the Kidney.—Dr. Simin, of Heidelberg, wounded the ureter of a woman in ovariotomy. A flow of liquid continued from the cicatrix in the abdomen, which was urine. He extirpated the kidney in consequence, with satisfactory results.

Cinchona.—The culture of the cinchona, or Peruvian bark, in St. Helena is progressing. The plants all look flourishing. There are now about 4,000 of them.

Apomorphia.—This new base, being free from narcotic properties, seems likely to become a valuable remedial agent.

Treatment of Epilepsy.—George Johnson, M.D., F.R.C., Physician to King's College Hospital, advocates chloroform in connection with bromide of potassium in this affection. Chloroform wards off a threatened fit, and cuts short a violent and prolonged paroxysm.

Burnett's Disinfecting Fluid.—Dissolve 200 grains of chloride of zinc in one pint of water, and bottle for use.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

MEDICAL REGISTRATION.

THOSE who have watched the progress of events in the medical world, for the past few years especially, have noticed that the profession are gradually dispensing with most of the old theories of reform and taking to more advanced liberal and practical ones. Among the former, that of legislative enactment for the protection of our rights and privileges has the smallest number of supporters. This is the natural result of the experience of the last half century. During that time, of all the laws that have been enacted for our benefit, hardly a single one exists which meets the design or intention of the original framers; while the others that have had more liberal and just provisions have been speedily and effectually repealed. In view of these facts, it must be conceded that all our hopes for reform must narrow themselves for the present to the limits of our own body, and that we must seek in our own way to stand on our own merits before the community. The idea is certainly tenable enough, and, considering the vast amount of work to be accomplished in the direction of taking care of our honor, dignity, self-respect, and usefulness to each other, we should for the present be satisfied to go no farther. The time has come when we are to properly discipline our army, that we may be able to act in a consistent manner on the defensive in regard to public opinion, rather than offensively in regard to our legislators.

One of the most feasible and satisfactory plans for initiating the requisite reformative measures is that of voluntary and thorough registration. Not long ago we remarked in a general way upon its importance, and we seize the present opportunity of again bringing up the matter, not only for the reason that the constant agitation of salutary measures is always beneficial for ultimate good, but because we believe that the medical opinion of the day is strongly in favor of the idea, and that we are at present in a better condition than ever before to carry it to a practical solution. From present indications we may consistently venture the assertion that the recent action of the Medical Society of the State of New York in regard to the measure is seconded by every other similar institution in the country. In fact there seems to be every argument in favor of it, and no forcible one against it. That the proper feeling is more or less universal, seems to be evident in the action of the American Medical Association for the past two or three years. A committee has been formed, of which Dr. Packard, of Philadelphia, is the present chairman, whose duty it has been to report upon some practical plan by which this proposed registration can be effected. That the time has come for a culmination of effort seems evident from the passage of the following at the last meeting but one of the Association:—

"*Resolved*, That each State Medical Society be requested to prepare an Annual Register of all the regular practitioners of medicine in their respective States, giving the names of the colleges in which they may have graduated and date of diploma or license."

Add to this the recent action of our State Society, to the effect that each county society shall look to the correct registration of medical men in its district, and it seems as if little else could be desired to insure the practical working of the proposed measure.

It is presumable that every respectable member of our profession, who is desirous of conforming with the letter and spirit of our Code of Ethics, is a supporter of some local medical society, whether of the county or district, and it would not by any means be an arduous task for the secretary of such an organization to give the authenticated list of the members. This much could certainly be done in the way of a beginning, and if it did no more than show to such as were not members of any society that the profession of the district were in earnest in their support of the system, very few, if any, of these would deem it to their interest to be considered outsiders. We care not how popular any medical man may be with his patients, how extensive may be his practice, or how large his income; if he be actuated by the proper motives, and be possessed of the proper education to take his stand with his brother physicians, he cannot afford to be looked upon with the suspicion of an irregular. The grand army medical, as such, has succeeded in gaining for itself during the past two thousand years too much reputation as an upright, dignified, and influential body to render it desirable for any straggler, under the plea of being progressive, to defy its discipline and fight on his own account. This, in fact, is so generally understood, that even the veriest quack knows how much of desirable respectability he can gain by identifying himself in ever so equivocal a way with the regulars. How much more must this be the case with such of our brethren as are merely lukewarm in regard to the proper spirit of the Code, by keeping aloof from all recognized association with the profession. We are not, however, at liberty to say, when a physician is not a member of some medical society, that he is not regular; but there is certainly room for a damaging aspersion against his proper standing.

It is but just to himself and the medical community in which he resides to give some reasonable explanation for his isolation. But correct as the principle and rule may be, we can, in view of the greatest amount of good to be obtained, allow of exceptions in the case of membership to societies, and permit all to appear on such a register as shall be approved worthy by the actual members of the societies of their localities.

The manner in which this registration must be carried out will insure for it, theoretically speaking at least, the greatest thoroughness, effectiveness, and impartiality. The basis of the system rests only upon truth, justice, and the purest of motives on the part of such as take the matter in hand. Nothing is compulsory, neither are individual rights interfered with in the slightest degree. The requisites for registration being, first, the possession of a medical diploma or medical license, and, second, compliance with the Code of Medical Ethics of the American Medical Association, in letter and spirit: only such as are known to fulfil the same appear in the list. The register made in conformity with such conditions only vouches for such names as appear in it, and nothing more. No medical man is compelled to show his diploma or license to any representative of a board of registry; he is only *invited* to do so, and if he does not see the necessity of complying, there the matter ends, and the said board cannot, of course, place his name among such as are known to have their degrees. The fact of the name being left out of the list does not, however, prove that the individual has not a diploma; there is only wanting positive evidence that he has such a document. The evidence of posession is, so to speak, strictly positive one way and entirely negative another. On the other hand, when an individual is known to have violated the Code, the board are not warranted in posting him as a quack, but are justified in withholding his name from among those who are known to act differently. This plan, when consistently followed out, relieves the registrar from all legal responsibility, while at the same time it makes it of much importance that any physician who desires to be considered respectable should have all doubts as to his true character cleared up as if it were according to law.

The obnoxiousness which naturally attaches itself to the workings of a limited and self-constituted tribunal is effectually removed by leaving all questionable cases to be decided by vote of the special society of the district. The publication of the list should be on the responsibility of the society rather than upon a committee or an individual, not only for the reason that it is just to the individual, but is more authoritative for the profession, by preventing the suspicion of partiality. We do not see how the thoroughness of this registration can be better guaranteed than by leaving it under the control of the county and district societies, as the members of such are always sure to know of any irregularities of behavior among their number, or of those who are only resident practitioners of the district. Aside from this, another good is accomplished in drawing with unmistakable distinctness the line between the questionables and unquestionables, a thing very much needed in many of our country districts; giving the former to understand that a tangible penalty has at last overtaken them.

Speaking generally of this system of registration, we think ourselves warranted in the opinion that the profession are willing to adopt it as authoritative, and that the time has come to inaugurate it in every State in the Union. As far as we can judge from the workings of the Medico-Historical Society of New York, in the establishment of the Medical Register of the City and County of New York, we can predicate a triumphant result for any other organization in any county that will labor as consistently, impartially, prudently, and decorously as has this Association. The time for mere experiment has gone by; the Association has demonstrated that trustworthy registration can be made in a district more populous than any other in the country, and we see no reason why in other counties, where the difficulties are reduced to a minimum, an attempt to follow the example is not at least warrantable. The benefit of this same registration has been incalculable to the profession of the Metropolitan district; every right-minded and honorable practitioner is in favor of it; and it is only those who have heretofore, and do still, show themselves unworthy of being in good company that speak against it. The sentiment of the profession here in regard to the usefulness and reliability of the system is such that there is no question as to the standing of such as are in the list, while a great deal of suspicion attaches to those whose names do not appear—a suspicion which, considering the care with which the work is done, cannot be explained on the score of the mere accident of omission. Aside from cementing the interests of the profession, and preventing a misunderstanding as to the true relation of physicians to each other, and to the community, numerous examples could be shown in which it has exercised a most salutary influence upon such as would otherwise have defied all restraint, admonition, or discipline. In a word, it is the silent censor of the profession, which, while it never condemns, never speaks well of any one unless he is deserving of it. Again we say, the profession are ready to endorse the movement; let the secretaries of the county societies show the proper and practical spirit in initiating it.

SINCE our last issue the trial of McFarland for the shooting of Richardson has terminated in a verdict of not guilty. The plea of insanity set up by the defence was well sustained, and too much credit cannot be given our townsman, Dr. W. A. Hammond, for the admirable manner in which he worked up the medical facts in the case, in the very face, too, of a very just prejudice against the usual medico-legal under-

standing of accountability in the premises. If there be such a disease as instantaneous insanity, this certainly is an instance of it. But why is such a sufferer allowed outside of a lunatic asylum? His trial and acquittal cannot have cured his malady, and another paroxysm may at any time end in the sacrifice of another human life. If it be just to acquit him, it is certainly very unjust to deny him the privilege of being cured of his dreadful propensity to kill in future. The community have a right to make for itself the same excuse as did some deferential boarders troubled with bedbugs:—"We pity the poor insects for having such proclivities, but really we have not the blood to spare."

Progress of Medical Science.

THE ADMINISTRATION OF CHLORAL.—J. M. Da Costa, M.D. (*Am. Jour. Med. Sciences*), in his "Clinical Notes on Chloral," thus observes: With reference to the action of chloral on coughs it is insufficient. Nor did it do any good in the only case of asthma in which he tried it. He has also been disappointed in its use in hiccough and in chorea. It is important to know that this powerful agent is not devoid of danger, and in every case we should administer it in tentative doses and carefully note its effects. It is contra-indicated in some diseases of the heart, and ought not to be prescribed for patients with feeble heart. Some of the unpleasant effects of the drug can be avoided by the simultaneous administration of opium. The two remedies can be used advantageously in some cases of delirium tremens, and when we wish to quiet pain. In conclusion, he believes that it is an important addition to our therapeutic means—chiefly, however, as a hypnotic. Its action as a destroyer of pain is limited, and it cannot compete with ether or chloroform in producing the insensibility requisite for surgical operations. Its chief value seems to be that of an auxiliary to opium, or to take its place when opium is not admissible. It is, however, not so certain; nor is it likely to displace that peerless drug.

BRONCHORRHAGIA AS INDICATIVE OF PULMONARY TUBERCULOSIS.—It was thought for many years that bronchorrhagia was indicative of approaching consumption; but Prof. John Ware has analyzed 386 cases in reference to this point, and demonstrated that no reliance can be placed on this symptom as showing the presence of tubercles, or even a tendency in that particular direction.

HUMULUS LUPULUS IN INTERMITTENT FEVER.—Dr. W. Y. Godberry, of Benton, Miss. (*The Jour. Materia Medica*), regards the anti-periodic power of humulus lupulus as equal to that of any other article in the Materia Medica, except quinia, and has often found it to succeed in arresting intermittents after quinia had failed.

QUININE IN LUMBAGO.—Dr. Glover recommends two-grain doses of quinine in lumbago every four or six hours, when other remedies fail. It is indicated only when the urine is clear.

SOFTENING OF BONES IN DISEASES OF THE BRAIN.—Dr. Clouston mentions that in some cases of death with aphasia, insanity, and general palsy, the bones become so soft that they may be easily cut with a knife.

GALL-STONES.—Dr. Nesfield, of Manchester, has had a case in which gall-stones passed through an abscess in the abdominal walls near the umbilicus. There was no jaundice, and the bowels acted regularly.

WAXED PAPER AS A SUBSTITUTE FOR OILED SILK.—Drs. Agnew and Hewson, of the Penn. Hospital, used waxed paper as a cheap and efficient substitute for oiled silk in surgical dressings. Ordinary thin tissue paper is passed once through melted wax and dried, when it is ready for use.

TRICHINÆ IN THE DOMESTIC FOWL.—Dr. G. S. Bryant reports having found embedded in the stomach and intestines of the hen large numbers of entozoa, coiled in cysts in every possible attitude, and not unlike the trichinæ found in the human muscle. He suggests that the disease known as "chicken cholera" is dependent on the presence of these entozoa, and promises to continue and report investigations on this subject.—*Richmond and Louisville Medical Journal.*

CAN SCARLET FEVER BE PREVENTED?—In reply to this question, Dr. Searcy, of Tennessee (*Trans. Tennessee Med. Soc.*), narrates several cases which came under his observation during several years past, showing, as he believes, that the tonsils are the parts through which the poison passes into the system. When the first manifestations of the disease are noticed, he applies at once a strong solution of nitrate of silver— 3 j. to water ℥ j. This is repeated twice daily for several days, with mild laxatives and proper diet, and in the majority of cases he believes that the disease may be mitigated or the threatened attack prevented.

BROMIDE OF POTASSIUM IN SACCHARINE DIABETES.—Prof. Austin Flint, Sr., reports in the *American Practitioner* three cases of saccharine diabetes in which he prescribed the bromide of potassium in 15 to 20 grain doses three times daily, with ordinary anti-diabetic diet, with very marked benefit. There was in each a rapid diminution of the thirst, a decrease of the amount and specific gravity of the urine to about a normal condition, and a corresponding improvement in the general health and condition of the patients.

ICE POULTICES IN TYMPANITIS.—Dr. Peter, Physician to La Pitié, Paris (*Med. News and Library*), employs a very efficacious and little-known method of subduing the tympanitic distention of the abdomen, so often an urgent symptom in typhoid fever, viz., the use of what may be called "ice poultices." Small fragments of ice are scattered over a thick layer of dry linseed meal; in this way a poultice is formed, which, in consequence of the slow melting of the ice, is kept at the temperature of melting ice. To Prof. Monneret belongs the credit of conceiving and introducing to the profession this very valuable method of treating tympanitis.

CASES OF AURAL DISEASE.—We extract the following from the "Statistical Report of Five Hundred Cases of Aural Disease," read by Dr. D. B. St. John Roosa, before the New York Academy of Medicine, and published in the *N. Y. Med. Journal:* The cases presented were seen within a period of three years and a half, and taken from his note-book without choice or omission. There were eight of circumscribed or furuncular inflammation of the external auditory canal. Seven of these recovered. The local treatment consisted of an early and deep incision of the swelling, and the subsequent use of warm water and leeches. The early incision was of the greatest service. The eleven cases of diffuse inflammation of the external auditory canal recovered. In some of these a slight irritation of the part had been nursed into a severe and obstinate one by the use of ear-spoons, hair-pins, and stimulating

applications. In these cases, astringents were used, usually either alum or sulphate of zinc. Four of the five cases of eczema of the external auditory canal were cured by the daily cleansing of the canal and surface of the membrana tympani, and the use of nitrate of silver, sulphate of zinc, and similar agents. Forty-six of the cases are classified as inspissated cerumen. The patients in these cases were all more than 16 years old. Forty-two were cured by the removal of the mass. It was usually found to exist in both ears, although the patient was not always aware of any trouble in but one. The table embraces twenty-one cases of acute, simple, or catarrhal inflammation of the cavity of the tympanum, affecting one side; eighteen of these recovered, one was improved, in one case the result was unknown, and one patient died.

We next come to those cases which are by far the most numerous in aural practice, those known as simple chronic inflammation of the middle ear, chronic catarrh of the middle ear, catarrhal deafness, or chronic myringitis. Of the 500 persons embraced in this table, 245, or nearly 50 per cent., were victims of this disease. Only 11 were cured. Only one of the cases occurred in an adult, a male. Seventeen were much improved, that is, the hearing power was recovered sufficient for all ordinary avocations; fifty-six were improved. The eustachian catheter was used for forcing common air, vapors, and fluids, into the cavity of the tympanum, or as an irritant to the mucous membrane. There were eight cases of acute suppurative inflammation of the middle ear, affecting one side only; six recovered. Of the same form of disease occurring on both sides, there was only one case which was cured.

He reports forty-five cases of chronic suppuration in the cavity of the tympanum, affecting one side only. Five of these were cured, that is, the discharge was stopped, the membrana tympani healed, and the hearing improved. There were sixty-six cases where suppuration existed on both sides; only two recovered. Fifteen were much improved, twenty-seven were improved, nine were unimproved after considerable treatment. A little more than one-fifth of all the five hundred were cases of suppurative inflammation. Of the deaths, four in number, two were children, one ten, the other sixteen years of age; two were adults, one sixty, the other forty-five. In one case the intense pain occurring at intervals, and which was supposed to be a consequence of the suppurative inflammation of the middle ear, which destroyed the hearing power on that side, was due to the influence of Bright's Disease, which was afterwards developed.

Ten of the patients presented were deaf-mutes. Three were cases of tinnitus aurium, without the slightest impairment of hearing or any lesion in the auditory apparatus. There were 297 males and 203 females in the cases presented. About 35 per cent. of the cases existed one year, or less, before being seen by Dr. Roosa; 21 per cent. existed between five and ten years; 16 per cent. between ten and twenty years.

AMPUTATION OF THE SCAPULA.—Dr. P. H. Watson, Edinburgh (*Edinburgh Med. Journal*), records, in a well-illustrated article, a case of amputation of the scapula, in which the patient, aged 13 years, had his arm torn off by machinery. The ligatures were soaked in a strong carbolic-acid solution. The wound was washed out with a weaker solution of the acid in water,—1 to 40,—and the whole cutaneous surface was covered with a plaster composed of one part of carbolic-acid lotion to seven of the emplastrum spread upon lint. The patient was discharged cured on the 74th day after the injury occurred. In regard to the employment of carbolic-acid dressings, he has no hesitation in saying that he has been disappointed in his expectations. The cases of this character published by Dr. Stephen Rogers, of New York (9 in number), with an operation by Dr. Blackman, of Cincinnati, narrated in the *Cin. Lancet and Obs.*, in 1858, and one reported by Vincent Jackson in the *British Med. Journal*, and a case not published by Prof. S. W. Thayer, of Burlington, Vt., including two amputations recently made,—one by Dr. Schuppert, of New Orleans, La., and the other by Dr. P. H. Watson, of Edinburgh,—all amount to 14 cases of this difficult operation.

INFANTILE CONSTIPATION. — Eustace Smith, M.D., London ("Wasting Diseases of Children"), suggests that daily frictions over the belly with the hand, or with some stimulating liniment, are also very useful in promoting a daily evacuation. Dr. Merriman recommends the addition of aloes to the liniment: ℞ Tinct. aloes co., ʒ ss; Linim. saponis co., ʒ j. M. ft. linimentum. This should be rubbed into the belly every morning. If the child is twelve months old, aloes given by the mouth is warmly advocated by the late Dr. Dunglison. A drachm of the powdered Socotrine aloes should be dissolved in an ounce of simple syrup; of this one teaspoonful may be given, and may be repeated, if necessary, until a satisfactory stool is obtained.

TURPENTINE IN INFANTILE CONVULSIONS.—When convulsions continue in colicky children, and are not relieved by the warm bath, injections of warm water, brandy, or chloric ether, with an alkali, Dr. Graves recommends turpentine to be given:

℞ Ol. terebinthinæ ..... ʒ j.
Ol. ricini ..... ʒ iv.
Mist. acaciæ } ..... ää
Aq. cinnamomi } ..... ʒ iij.

M. ʒ j tertiâ quâque horâ.

This acts on the bowels, and produces a copious discharge of urine. — *Smith's Wasting Diseases of Children.*

THE DERMATOLOGICAL CLASSIFICATION.—In the year 1780, Plenck, the Hungarian nosologist, laid fully the foundation of modern dermatology, and gave his classification to the world.

DOSES FOR HYPODERMIC USE.—The following formulas for hypodermic injection have been recently prepared for a new Visiting-list:

Aconitine (*Aconitin, Off.*)—℞ Aconitine, gr. i.; aquæ destillatæ purissimæ, f ʒ ss. Misce et fiat solutio. Dose: *minimum*, ♏ ij. = $\frac{1}{120}$ gr.; *maximum*, ♏ iv. = $\frac{1}{60}$ gr.

Atropine (*Atropia, Off.*)—℞ Atropiæ sulphatis, gr. i.; aquæ destillatæ pur. f ʒ ss. Misce et fiat solutio. Dose: *minimum*, ♏ ij. = $\frac{1}{120}$ gr.; *maximum*, ♏ iv = $\frac{1}{45}$ gr. Adapted to pain in pelvic viscera.

Caffeine, Theine.—℞ Caffeinæ, gr. ij.; aquæ destil. bullientis, ♏ lxxx. Misce et fiat solutio. Dose: *minimum*, ♏ 20 = ¼ gr.; *maximum*, ♏ 40 = 1 gr. Neuralgia and alcoholic insomnia.

Strychnia (*Strychnia, Off.*)—℞ Strychniæ sulphatis, gr. ij.; aquæ destil. bullientis, ʒ i. Misce et fiat solutio. Dose: *minimum*, ♏ ij = $\frac{1}{120}$ gr.; *maximum*, ♏ iv = $\frac{1}{60}$ gr. Gastralgia and neuralgia of heart.

Morphine (*Morphia, Off.*)—℞ Morphiæ acetatis, gr. v.; acetici, ♏ i.; aquæ destil. bull. f ʒ i. Misce et fiat solutio. Dose: *minimum*, ♏ i. = $\frac{1}{15}$ gr.; *maximum*, ♏ vi. = ¼ gr. Ten drachms to a drachm can be dissolved by use of glycerine. Especially useful in delirium tremens and neuralgic pains.

Nicotine (*Nicotina*).—℞ Nicotinæ, gr. i.; aquæ destil. puris. f ʒ ss. Misce et fiat solutio. Dose: *minimum*,

♏ij. = $\frac{1}{120}$ gr.; *maximum*, ♏iv. = $\frac{1}{60}$ gr. Useful in tetanus.

Digitaline (*Digitalia, Off.*)—℞ Digitaliæ, gr. i.; aquæ destil. puris. f ʒ ss. Misce et fiat solutio. Dose: *minimum*, ♏ij. = $\frac{1}{120}$ gr.; *maximum*, ♏iv. = $\frac{1}{60}$ gr. Good in febrile conditions.

Calabar Bean (*Physostigma venenosum*).—℞ Extractum physostigmatos venenosi alcoholici, gr. ij.; aquæ destil. purissimæ, ʒ ij.; glycerinæ, ʒ i. Misce et fiat solutio. Dose: *minimum*, ♏20 = $\frac{1}{15}$ gr.; *maximum*, ♏40 = $\frac{1}{8}$ gr. In tetanus.—*Cin. Med. Repertory.*

Treatment of Acute Myelitis.—C. B. Radcliffe, M.D., F.R.C.P. (*Med. News and Library*), in his entertaining article on "Diseases of the Spine and of the Nerves," advocates but little active treatment in *acute myelitis*, but thinks that sesquichloride of iron would be likely to be of more real service than iodide of potassium. For his own part, he confesses to a feeling which makes him hesitate to employ either belladonna, or ergot, or strychnia in myelitis, or in any analogous condition, until he knows more of their action, or until he has more unequivocal empirical evidence of the good resulting from their use. Dr. R. is disposed to trust chiefly to full doses of this preparation of iron, to food and wine in no stinted quantities, and to the position recommended by Brown-Séquard for draining away blood from the spine,—a position in which the patient is made to lie upon his abdomen or side, with his hands and feet in a somewhat dependent position.

Almost Complete Ossification of the Human Body.—A singular case of ossification of the body of a youth is published by Wm. M. Byers, M.D., Columbus, Texas (*N. O. Journal of Medicine*): A boy of 17 came under his notice first about four years ago with extensive ossification of the muscular system, which continued to progress till his death, which occurred recently. He was a stout child at the age of eight months, at which time his parents removed to Texas by land. While camping out tumors were noticed in different parts of his body, the size of small marbles, very hard and painless. After an interval of 12 or 18 months, the tumors began to disappear by absorption, and stiffness of joints was manifested. Gradual anchylosis followed, and at the age of 10 years the hip joints and arms were completely anchylosed. He did not increase in stature after his tenth year. The deposition of ossific matter continued during his life, and when he died he was almost complete bone. Up to the hour of his death his mind continued clear and unimpaired, and his digestion until a short time previous was excellent. He suffered no pain, and was cheerful and happy.

The Principal Opposing Force in Dislocations.—Prof. Wm. Warren Greene, M.D. (*The Boston Med. and Surg. Journal*), believes that the main opposing force to the reduction of dislocations is the untorn portion of the capsular ligament; that in our efforts at reduction the primary object should be the relaxation of the untorn portion of this ligament, and that whatever mode of procedure accomplishes this with most facility is the best; that occasionally the small size or peculiar shape of the rent in the capsule, or, in peculiar conditions of the nervous system, muscular contractions, may constitute the major forces with which we have to deal; but that these cases are so extremely rare as not at all to invalidate the general rule.

Upon the theory that muscular contraction is the most powerful opposing force to reduction, a very large proportion of the difficult cases must remain unexplained; but upon the assumption that the untorn portion of the capsule is the principal agent with which we have to deal, everything becomes clear.

Morbid Growths within the Larynx.—A. Ruppaner, M.D., N. Y. (*N. Y. Med. Journal*), reports the removal of four cases of morbid growths within the larynx, and adds that there are several *desiderata* upon which the success of this distinct class of operations must depend. Some of these are yet to be solved satisfactorily, while others depend solely upon patient and operator.

1st. The want of a sure and safe local anæsthetic, to be used during operations within the larynx, is severely felt. Tobold uses cold water or strong alum injections, applied through one of Mathieu's or Lewin's *pulvérisateurs*. Dr. R. has found this method the most satisfactory in his practice. More than upon the action of anæsthetics the result of the operation depends, 2d, upon the due preparation of the patient for the operation, his individuality and disposition, the space and form of the larynx. 3d. The extent of the growth, and its mode of insertion, demand consideration, as elements entering into an operation. Every attempt to destroy a polypus by caustics is to be deprecated. 4th. In operations of this nature, the surgeon must act with skill and perfect composure. The left hand must be as serviceable as the right in using mirrors and instruments. A good light to illumine the throat and larynx must be commanded. In conclusion, he states that the admirable apparatus of Tobold, with three lenses, cannot be surpassed in simplicity, steadiness of light, and power.

Treatment of Aphthæ.—Eustace Smith, M.D., London, in his valuable treatise on "Wasting Diseases of Children," recommends, if *aphthæ* form, that attention be paid to cleanliness. A powder of rhubarb and jalap, with a grain of hydrargyrum cum cretâ, should be given to evacuate the bowels; after which the following mixture should be prescribed: ℞ Potas. chloratis, ↄ ij; Syrupi simpl., ʒ ss; Aquæ ad ʒ iij. M. ʒ ij quartâ quâque hora. This must not be diluted. When attacks of acute indigestion come on in infants, with hot skin, furred tongue, thirst, vomiting, and diarrhœa, accompanied by griping pain, all food must be stopped, and nothing allowed but cold barley-water. The stomach should be relieved by an emetic of ipecacuanha, after the action of which a purgative of rhubarb and magnesia should be given to clear out irritating matters from the bowels. A mixture of chalk and catechu, with aromatic confection, can then be given, or the following: Bismuthi nitratis, ʒ j; Pulv. cretæ aromat., ʒ j; Syrupi, ʒ ss; Mucilag. tragacanth., ʒ ss; Aquæ ad ʒ iij. M. ʒ ij ter die. If the diarrhœa continues after the tongue has become clean, half a drop of laudanum can be added to each dose of either of these mixtures, or small doses of sulphuric acid may be given with opium. ℞ Acidi sulphurici aromat., ʒ ss; Tinct. opii, ♏ vj; Syrupi, ʒ ss; Aquæ carui, ad ʒ iij. M. ʒ ij ter die.

When the irritability of the stomach has subsided, milk and lime-water may be given, but with caution, lest the vomiting return.

On Seatangle Tents.—Dr. Braxton Hicks, Physician, Accoucheur, and Lecturer on Midwifery at Guy's Hospital, in an interesting article "On Seatangle Tents," published in the *Practitioner*, points out the special advantages of tents made of *seaweed:*

1st. They can be made of any size, particularly much smaller than sponge-tents. 2d. They have more distending power. The rigidity of the inner os uteri is sometimes so great that even these tents are distinctly marked by it; but the sponge tents not at all unfrequently are unequal to produce any marked impression on the constriction. 3d. They do not retain the se-

cretions so as to produce so much offensiveness, consequently there is less risk of irritation locally or generally. 4th. By their greater rigidity they can be more readily applied, especially in a tortuous canal.

They have, however, some disadvantages: Their rigidity makes them not so suitable in cases where the uterus is bleeding or very tender; nor in cases where the os is somewhat dilated by a polypus or growth distending it. Here a sponge tent is best, unless the os and cervix are very rigid. Their great distensive force makes them less acceptable when the uterus is very irritable. They should be in all cases so made that no sharp edge be noticeable. In the tubular tents this is a point liable to be overlooked. And for the dilatation of the os uteri in a natural state, for purposes of induction of premature labor, these tents are not by any means so suitable as the sponge tents, or the India-rubber bags. With these exceptions, in cleanliness, certainty of action, ease of introduction, and minuteness, they are certainly not equalled by any other material at present in use.

Onychia.—Brice Smyth, M.R.C.S.L., Surgeon to the Belfast General Dispensary (*Jour. of Cutaneous Medicine*), states that *traumatic onychia* is more common in Belfast than in any other of the large manufacturing towns of England or Scotland; and this he attributes to the fact that the workers in the flax-spinning mills of Belfast usually go barefooted when at work, while at Leeds, Dundee, and other centres of the flax-spinning trade, they are accustomed to wear clogs or shoes. The disease usually attacks girls of a strumous or cachectic condition of system, and always those employed in the spinning-room; the nail of the great toe is the part usually affected.

The treatment of this form of Onychia must be both local and constitutional. The plan recommended by Dr. H. S. Purdon he has found very successful: Excision of the nail, followed by a lotion of one drachm of Fowler's solution to two of water. Sir Wm. Ferguson recommends, if the disease be seen in the earlier stages, the nail to be properly pared, or a section to be taken from it, and an application of nitrate of silver to the diseased part. In the majority of cases occurring in mill-workers there is more or less "nervous irritability," and in such individuals irritating applications tend to increase the local disease; consequently he has found that opium as a constitutional remedy and local application is the drug which he would place most reliance on in the earlier stages. When the nail has to be removed, which in the majority of cases is uncalled for, the ether spray should be used. Dressing the raw surfaces with carbolized oil, prescribing for the patient cod-liver oil and iron, will usually bring about a speedy cure.

Action of Viridiæ Sulphas.—Horatio C. Wood, Jr. M.D., Prof. of Botany in the Univ. of Penn. (*Am. Jour. Medical Sciences*), asserts that the commencing dose of viridiæ sulph. may be set down at the sixth of a grain, repeated every hour, and increased until the desired end has been reached. He has never observed any marked cumulative effect, and believes the alkaloid to be pre-eminently safe as compared with other remedies of equal power, *i.e.*, it would be much safer to reduce the pulse rapidly 20 beats per minute, and the force of the blood stream correspondingly with it, than with any other known remedy. The alkaloid (viridia) has all the properties and the peculiar sedative influence of veratrum viride, without the horrible nausea and vomiting which always occasion so much discomfort, and which in some instances endanger life.

If any case of poisoning from it should arise, the treatment should be such as would be suitable were veratrum viride itself the agent—perfect quiet in the horizontal position; brandy and ammonia freely; opium, or atropia cautiously; and, on general principles, strychnia.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 11, 1870.

Dr. J. C. Hutchison, President, in the Chair.

MORBUS COXARIUS, ETC.

Dr. Hutchison exhibited a patient aged 19, with specimens. Said patient entered the Brooklyn City Hospital eighteen months ago for a disease of the hip-joint, and stated that, when three years of age, he fell upon the left hip-joint, which so disabled him that he was compelled to use crutches for several years, and subsequently a cane. When he entered the hospital the leg was flexed upon the thigh, and the thigh was flexed upon the pelvis at an angle of forty degrees, and the leg was strongly adducted. Six weeks before his admission an abscess appeared behind the trochanter major, which opened, as did also another on the inner and upper portion of the thigh, with fragments of bone. At this time he was much emaciated and extremely feeble, so that he was confined to his bed until the operation.

By the use of tonics, cod-liver oil, etc., his general condition sufficiently improved to justify the operation. An incision was made from the ileum over the trochanter a distance of ten inches, exposing the upper portion of the femur. It was then ascertained that the head of the bone had disappeared, and that there was a diseased condition of the bone extending from the tip of the trochanter major down a distance of four inches. This was removed by the saw. It was found necessary to take away a large portion of the external table of the ileum, with considerable diploë. The knee was forcibly straightened, and the whole limb brought down and maintained in the proper position, by means of weights, the long splint and adhesive plaster, etc. The motion at the hip and knee joints was very limited, but at the time of reporting the case that of the knee-joint was quite perfect, and there was a great improvement in the hip-joint. The recovery was very tedious, but he was now able to follow his vocation of a cook, and walk around by the aid of a cane and stirrup. This latter measured six and three-quarter inches, but patient believed he could use one an inch shorter. The leg was in its proper position. The operation was performed sixteen months ago.

RESECTION OF SHOULDER-JOINT.

The President also presented the head and upper portion of the humerus, which he removed from a gentleman thirty-five years of age on the eighteenth of March last. This patient first came under the observation of Dr. John P. Gray of the State Asylum, Utica, who sent him to Dr. H. for treatment. Three years ago some pain in the shoulder had been complained of, attended with considerable swelling, which continued for several months. Finally, a discharge of matter occurred just above the outer portion of the clavicle, and also on the inner and upper portion of the arm. This was two and a half years ago. The pain was very much less than that usually found in joint affections in which the synovial membrane is primarily involved. Every possible attention was paid to his general health,

and while travelling abroad he consulted a surgeon of Bristol, who probed the upper opening with apparently an unsatisfactory result. When he presented himself to Dr. H. the openings gave the appearances of dead bone underneath, although none was detected with the probe. The patient was told that there was probably disease of the shoulder-joint, which should be removed. He consented to be anæsthetized for a more careful examination, and to have the parts excised in case the diagnosis was confirmed.

A straight incision was made from the acromion process down through the deltoid muscle, the muscles attached to the greater and lesser tuberosities cut loose, and the dead bone turned out and sawed off. At the point of the first section, the bone being found diseased, the saw had to be applied successively lower down until four inches in all were removed. A small piece of necrosed bone was also found in the centre of the glenoid cavity, which was detached and removed with an ordinary dressing-forceps. The arm was put up in Pomeroy's splint, a most excellent apparatus for this purpose.

Some of the periosteum was left in this case, but not as much as desired.

OVARIAN CYST.

Dr. Finnell presented a multilocular ovarian cyst taken post-mortem from the body of a lady seventy-three years of age. Five years ago she first noticed a gradual increase in the size of her abdomen, which continued until a year ago last April, when Dr. F. first saw her. She appeared then like a person suffering from ordinary ascites. She was tapped in the course of the year following twelve times. The following were the respective quantities, in pounds: 26, 20, 21, 19, 23, 25, 20, 19, and 18; making in all 245 pounds. At first it seemed as if there existed but cyst, as the whole swelling seemed to collapse after the tapping, but it was subsequently evident that lesser ones developed from the walls. The point of interest in the case was the small amount of adhesions present, and the breadth and thinness of the pedicle. The tumor after its removal weighed forty pounds. Barring the age of the patient, the case would have been an exceedingly favorable one for operation. The opposite ovary was in a perfectly healthy condition. In conclusion, he remarked that he tried to produce sleep in the patient, but failed with morphine, and succeeded perfectly with ten-grain doses of the hydrate of chloral.

Dr. Robinson asked if much sweating followed the administration of the latter remedy, and being answered in the negative, stated that he had a case in which that condition was very marked.

AORTIC ANEURISM.

Dr. Briddon exhibited a specimen of aortic aneurism removed from the body of a German 44 years old. He had enjoyed good health until a year ago, when he began to be troubled with cough; two months ago his cough became worse, and was accompanied with considerable expectoration and hoarseness. In the early part of April the expectoration was occasionally tinged with blood; he continued to work at his trade until the 20th of April, when he left for home and retired at an earlier hour than usual, complaining of feeling unwell. On the morning of the 21st he was found in bed, bleeding from nose and mouth, and unable to articulate. During the forenoon he became insensible and was seen by a medical man. Late at night he had another severe hemorrhage from nose, mouth, and bowels, and two other attacks before 9 A.M. on the morning of the 22d, when he died.

Inspection of the body found all the tissues blanched. Stomach was enormously distended with blood-clot, estimated at about a quart; intestines also contained blood in less quantity. Liver was slightly cirrhosed. Lungs contained no cavities, but the cicatrices of old ones. Heart was hypertrophied; valves sound. Second portion of aortic arch was dilated into a large aneurismal sac, or into two saccular pouches, separated by a constriction occupying the site of origin of brachio-cephalic vessels; the larger compartment lies in the concavity, but slightly in advance of the arch; its walls are considerably thickened; the smaller compartment lies immediately in front of trachea and œsophagus, and it has opened into the latter tube by a process of slough; its walls are thin and unsupported by adventitious tissue.

SUB-PERIOSTEAL EFFUSION OF BLOOD.—SEPARATION OF EPIPHYSIS, ETC.

Dr. Weir presented the lower extremity of a male child, aged one year, who died the day before at the Nursery and Child's Hospital. His attention was first called to the knee the beginning of the present month. An examination proved the joint to be sound, but that there was a swelling extending a considerable distance up the left thigh, which was most marked about an inch above the articulation. Grasping the leg and upper part of the joint, and making a slight alternate movement, slight crepitus was discovered. This trouble had existed three weeks in the child. He believed it to be a separation of the epiphysis consequent upon periostitis, coupled in all probability with osteo-myelitis, an opinion confirmed by the autopsy. The child had been run down very much by a pneumonia that had existed for two or three months, and also entero-colitis.

On removing the leg just below the knee, he was struck with the fact that the knife plunged through recently effused material. The periosteum was stripped up from the tibia for an inch to that point, and filled by a clot; the same condition of things extended to the ankle. From the fact that the clot surrounded the bone it seemed evident that the change was ante-mortem, the co-existence of a hemorrhagic diathesis helping to support such an opinion. The patient had previously suffered from rachitis.

SCIRRHUS OF PYLORUS, ETC.

Dr. Sprague, of Fordham, presented specimens of stomach and intestines removed May 1, from a female patient who first presented herself to him on the ninth of April. She had not had her catamenia since the July previous, and had been told she was pregnant. On a superficial examination of her swollen abdomen he was enabled to assure her to the contrary. She was very much emaciated, very feeble, and was just able to walk about; had been suffering a good deal for two or three days from nausea and vomiting. At first there was a good deal of tympanitis, which was afterwards replaced by serous effusion in the peritoneal cavity. Her urine was found loaded with albumen, and contained besides quite an amount of epithelial scales. She was put upon a course of hydragogue cathartics and diuretics without any very favorable result. Diarrhœa subsequently appeared and interfered with this plan of treatment, the discharges two or three days before death assuming a dark-greenish color.

At the autopsy, four hours after death, the heart and lungs were found healthy. The peritoneum contained two quarts of serum. The stomach was enormously distended with fluid of a dark-green color. The py-

loric extremity was the seat of a scirrhous cancer, which faded off towards the cardiac end. The gall-bladder was entirely impervious, and was reduced to the size of the finger. Over the whole surface, especially towards the mesenteric attachment, there were to all appearances small tubercular masses evidently subperitoneal. The peritoneal membrane was very much thickened, especially posteriorly. The valvulæ conniventes were curiously disposed, their long axes running in a direction opposite the usual one. The left kidney was the seat of tubular nephritis; the right was healthy. There were no tubercles in the intestines, nor in the lungs.

He exhibited the specimens for the sake of having it determined whether or not the masses supposed to be tubercular were really such, and moved that they be referred to the Committee on Microscopy.

The Society then went into executive session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, APRIL 4, 1870.

DR. GEO. T. ELLIOT, PRESIDENT, in the Chair.

THE President announced the admission to membership of Drs. Henry E. Henderson, Horace T. Hanks, Joseph A. Monell, Simeon N. Leo, and Ralph L. Parsons. He reported the death, on the 2d inst., of Dr. Galen Carter, a member of the Society since 1828, and its President in 1853.

The report of the Committee on Intelligence was read by Dr. Thompson, and that of the Committee on Diseases by Dr. Raborg.

The weather being very inclement, and the attendance small, Dr. Austin Flint, Jr., moved that the reading of Dr. Lusk's paper on *Sugar-Formation in the Liver*, announced for this meeting, be postponed to a more favorable evening. Dr. Lusk expressed his readiness to read the paper to the present audience, but Dr. Flint's motion prevailed, and the President then called upon the mover to occupy the hour, suggesting as his subject the

PHYSIOLOGICAL EFFECTS OF MUSCULAR EXERCISE.

DR. FLINT, Jr., said that, upon so sudden a call, he could not be expected to give the subject any elaborate or systematic treatment; but it was one to which he had devoted considerable attention, and he would present some points which, though not wholly new, might yet not be without interest.

It was hardly necessary to state that the nutrition of the body is carried on in obedience to the demand created by the waste of its different tissues; and the fact was familiar to all physiologists of the present day that a physiological increase of this waste, within certain limits, not only promotes a more active nutrition of the several tissues, but also serves to develop what may be called their vital properties. To consider only the muscular system, which constitutes so large a portion of the organism, we know that muscles called into frequent exercise increase in size and power—the finger-muscles of the pianist, for example, become extraordinarily developed—while muscles less exercised are correspondingly weak. If any muscle is entirely disused, it undergoes atrophy, and after a certain time becomes reduced to such a condition that it is incapable of regenerating itself, even though the blood may contain all the materials necessary for its full nutrition. Paralysis illustrates this. When the nervous supply of a muscle is cut off its fibres become weaker, its circulation is diminished, and after a time we find, under the microscope, that the proper muscular substance—the musculine—has been replaced by a material physiologically inert, fatty granulations. By and by these granulations so far take the place of the functioning muscular substance, that even if the nerve-power be restored to it, the muscle cannot resume its function. The practitioner familiar with nervous diseases is well aware of this; and in a case of paralysis he first of all ascertains whether the affected muscles will respond to the stimulus of electricity. If they will so respond, then, even though all power of voluntary contraction be for the time lost, the methodical application of this stimulus will serve to maintain and increase nutrition, and, as a rule, the restoration of function is possible. But if it be impossible to make the muscles contract, however feebly, then there is little hope from any treatment. Diagnosticians go further, and, by the aid of a small trocar or harpoon, remove a little piece of the muscle for microscopic examination. In the muscles which show any contractility, they find the fibres with their characteristic striations, though mixed with the fatty granulations; while in those which show none, the fatty matter is found almost alone.

Muscular exercise increases the quantity of excrementitious matter produced in the system. On this point the speaker had no doubt, although there were some observations which might seem to show that exercise does not augment the amount of urea discharged in the twenty-four hours. Prominent among these were the well-known experiments of Fick and Wislicenus in their ascent of the Alps; and their results would seem lately to have been corroborated by Professor Haughton. These observations, when first published, the speaker had been disposed to receive with a good deal of doubt, and to examine critically for sources of error. For if urea be the most important of the excrementitious principles, as regards quantity, and if it be not increased, but rather diminished, by violent exercise, then we must make over again our physiology. Fick and Wislicenus, instead of comparing the discharge of urea under ordinary conditions of exercise and diet with that after extraordinary exercise upon ordinary diet, compared it with that after extraordinary exercise upon non-nitrogenized diet. Yet it is well recognized that the amount of this excretion depends in great measure upon the character of the food ingested. Professor Haughton's experiments were even more loosely conducted. He obtained his normal discharge of urea under ordinary conditions from observations made some years before, and compared this with the amount discharged (in the urine) under violent exercise taken in the heat of summer, and exciting profuse perspiration. Now urea is a constant constituent of the sweat; and Speck and others have established the fact that where violent exercise is taken under such conditions as to induce great diaphoresis, the amount of this principle eliminated by the kidneys may suffer no increase but even diminution, the skin relieving the kidneys of a portion of their work.

These experiments, therefore, by no means prove that muscular exercise does not increase the amount of urea discharged from the system. And in the same category are to be placed the observations of those who claim that extirpation of the kidneys does not produce accumulation of urea in the blood. If it is not established that urea is an excrementitious principle brought by the blood to the kidneys and simply eliminated by them—not *secreted* by the kidneys from materials furnished by the blood,—then all our experimental physiology is of little worth.

It seems certain, then, that exercise increases the

amount of effete matter eliminated. Within physiological limits, this increased elimination is attended, if proper nutriment be presented in the blood, by an increase in the activity of nutrition. If a man in perfect health, eating and drinking according to undepraved tastes, exercise his muscular system so as to increase to the highest physiological point the elimination of effete matter, he will correspondingly increase the nutrition of his muscular system. Nutrition consists in the appropriation by the tissues, from the blood, of new *functioning* matter,—in the case of a muscle, of musculine, in place of the worn-out matter discharged as urea, creatine, creatinine, etc.—not in the deposit of a functionless material, like fatty granulations. The more active this appropriation and the greater its amount, the higher will be the state of development of the muscle, and the better will it be able to do its work.

Now, if we can thus develop the functional capacity of the muscular system, and bring it to the highest point of efficiency, it is not unreasonable to suppose that the rest of the body will share in the improvement. We have, for example, an increased consumption of oxygen, an increased production of carbonic acid, and so increased functional capacity of the lungs.

Can a man, by such exercise, successfully combat the tendency to the deposit of foreign substances in the tissues; can he avert, for instance, the production of such heterologous formations as tubercle? The speaker, although from a limited experience, felt confident in answering "Yes." He had seen men of tuberculous diathesis, and with tubercle already deposited in their lungs, as testified by the best diagnosticians, go to the gymnasium and become hale and strong. He had in mind a young man, a patient of his father's, who had become a most accomplished gymnast after pulmonary tuberculosis had been clearly diagnosticated. In view of the principles before spoken of, it would seem that these men might, by increasing the deposition of normal material, have removed the disposition to the deposit of abnormal material. The speaker had, of late years, taken a special interest in examining this matter, for he had himself been subject to an affection which he thought might be relieved, and its effects averted, by systematic exercise. He had made trial of the plan, had been very constant and regular in his exercise, and had experienced the happiest results.

Let a man, moderately healthy, work as hard as he please with his brain,—if only he take the appropriate exercise to keep the system throwing off all the effete matter, and appropriating, in place of it, healthy, nitrogenized, functioning matter, he will be comparatively safe. It is surely better to be thus recruiting every day, and keeping one's self in a state of constant efficiency, than to break down every few months or years, and have to take a vacation to build up again.

Dr. Neftel, being called upon, spoke of the high standing of Fick and Wislicenus among physicists and physiologists, and of the real object of their experiments, which was to prove that in muscular exercise hydrocarbons are chiefly consumed, and to compare the mechanical power so generated with the amount of heat produced by their oxidation. As to the reaction of paralyzed muscles to electricity, it depended much upon the cause of the paralysis. In cerebral paralysis, the electro-muscular contractility was increased, as shown by Marshall Hall. In spinal paralysis it was diminished, though to this there were exceptions. In peripheral paralysis it was diminished to the induced current, but often increased to the galvanic current. These differences were so characteristic as to serve for diagnosis of the place of lesion in paralysis.

Dr. Folsom inquired of Dr. Flint whether the increase of a muscle in size was due to a deposit of sarcous elements within the existing fibres, or to an addition of new fibres. The latter would seem to be a higher process, as implying an increase of the formative force of the body—that force which determined the shape and size of all its organs. He wished to ask also the effects of muscular exercise upon the vaso-motor nerves; and the comparative effects of light and heavy exercise.

Dr. Flint, Jr., said that the first question, as to the mechanism of a muscle's growth by exercise, he did not think it possible as yet to answer definitely; though the view most in favor with the best pathologists seemed to be that no new fibres are developed, but that the muscle increases in size by the increase in size of its existing fibres. It was certain that the muscular fibres of men were larger than those of women, and those of a strong man larger than those of a weak one.

The second question he would not attempt to answer. Our knowledge of the vaso-motor system was still too imperfect. As to the relative value of light and heavy gymnastics, there were great differences with different individuals. It was probable that the very light exercises, such as swinging wooden dumb-bells or the lightest clubs, would effect comparatively little in the way of muscular development. The very heavy exercises—lifting weights of six or eight hundred pounds between the legs, putting up dumb-bells of seventy, eighty, a hundred pounds—though developing enormous power in a special direction, did not well develop the system generally. The men who could do these feats could do these alone—they were stiffened for everything else. The exercises which professional gymnasts found the best for their general development were those of a moderately heavy character continued for a long time,—the pulling of weights, or the swinging of dumb-bells, weighing eight or ten pounds, for hundreds of times. Such exercises were very fatiguing, and their practice developed great endurance.

Dr. Chadsey had found well-directed exercise an invaluable therapeutic agent in numerous cases of pulmonary and other diseases, some of which he related. The exercise should be such as to increase the flow of blood to the diseased part, and in affections of the lungs such as to develop the muscles of respiration. In a case of advanced muscular atrophy, exercise, dry heat, and electricity were bringing about a rapid restoration.

The President was profoundly convinced that one of the most important elements of success in solving the difficult problem of the treatment of diseases of women, consisted in securing such a mode of life as would compel muscular activity and so equalize the circulation. For many patients he was in the habit of ordering localized movements, shampooing, etc., until they were able to take out-of-door exercise. In a large class of cases of anæmia and amenorrhœa, where the patients complained of weakness, wanting to keep in the house and loll on the sofa, he had more confidence in this physiological mode of treatment than in all others. If this were properly followed out, the local treatment now so much in vogue, and the ever-ready resort to the speculum, might commonly be dispensed with.

The President announced the names of the delegates to the American Medical Association, after which the meeting adjourned.

Syphilides.—This affection comprises, on an average, about one-eighth of all skin diseases.

Correspondence.

ATROPINE VERSUS OPIUM.

To the Editor of the Medical Record.

Sir—I send you the following "Notes" as further proof that we have in Atropine a ready, safe, and reliable antidote to the poisonous effects of opium:—

April 11th, 1870, at seven P.M. was called to see Mrs. S. W——, American, twenty-nine years of age, of frail build, but in good general health. Had known her to be of intemperate habits, and had several times seen her in convulsions apparently from the effects of excessive indulgence in ale. Found her motionless, comatose, pulse 120 and feeble, no power of deglutition; pupil "contracted to a point;" respiration six to eight per minute; inspirations short and stridulous; countenance livid; frothy mucus escaping from the mouth; sensibility destroyed. On inquiry found she had long used morphine from habit, and that at three P.M. she had obtained at a drug-store and taken at one draught three grains of the drug. When found at six o'clock she could with difficulty be kept awake, although answering a few questions intelligently. Soon after went into the condition described above.

Ordered sinapisms to extremities and spine, and as soon as possible, or at 7.30 P.M., prepared and injected hypodermically into the inside of the forearm one-sixteenth ($\frac{1}{16}$) of a grain of sulph. of atropine dissolved in equal parts of alcohol and water, the whole quantity thrown in amounting to fifteen drops. Pulse at that hour 120; respiration eight per minute; inspiration short, sharp, and guttural; pupil contracted to its utmost.

8 P.M. Pupil a trifle larger, and evidently feeling the atropine; respiration 12; pulse 112.

8.30 P.M. Pupil dilated to the size usual in a shaded room; respiration 17; pulse 112; lividity much cleared up.

9 P.M. Pupil widely dilated; respiration 18; pulse 120 and very feeble; lividity of countenance but slight.

9.30 P.M. Same. Respiration short and stertorous; pulse very feeble at the wrist.

10 P.M. Pulse 120 and fuller; respiration 14; inspirations full and wavy, but loud snore heard over the whole house; color and heat returning to the forehead and cheeks; extremities cold; pupils widely dilated; mouth moistened naturally by saliva.

10.30 P.M. Respiration 20 per minute; inspiration much shorter than at last entry, with the sharp, stridulous, croupy sound; pulse 112 and very feeble; countenance pale but not livid; extremities cold; pupil as before, well dilated; no sensibility of surface; jaws rigid.

11 P.M. Has improved much in last half hour. Resp. 15; insp. full and easier, but croupy; pulse 120, and much improved at the wrist; heat of head normal, and warmth returning to extremities; pupils a trifle less dilated; no response when subjected to strong light.

11.45 P.M. Remained as at last entry until 11.25, when breathing almost ceased, pulse went down, and countenance became livid. Resorted to artificial respiration for 15 minutes with marked relief. At this hour respiration is 7 per minute and full; pulse 140, and becoming stronger and fuller; color and heat returning to face; pupil as before.

12 midnight. Pulse 120, fuller; resp. 10; pupil same; heat of head good, and color improving; inspiration deep but noisy.

12.30 A.M. During last half hour resp. remained at 10. At this hour it flagged again, but artificial respiration has again restored it to 10 per minute, with pulse at 152; extremities warm, pupils slightly less dilated. No response yet obtained by pinching or pricking the surface, tickling the nostrils, or touching the eyelashes.

1 A.M. Same as last note.

2.30 A.M. Have slept myself since last entry. All has gone on well; pulse now 132, quite full; resp. 8 per minute; inspiration deep and smooth, the whistling sound having ceased; pupil contracted to nearly normal size, but uninfluenced by the light of a kerosene lamp; titillation of eyelashes produces some muscular action of the lids, but a feather placed in the nostrils has no effect; countenance flushed, and general natural warmth over the whole body.

3 A.M. Pulse 136, and full; resp. 10, smooth and free from stertor; pupil but slightly larger than natural; surface warm and moist with perspiration. Will now leave the patient with some confidence that the danger of fatal result is passed, but to be called if bad symptoms return.

8.30 A.M. Found patient wide-awake and wondering at the strange stories of the night past. Learned that half an hour after I left (3 A.M.) patient suddenly roused up and vomited freely a very black, thin, watery substance. Then slept until 7 A.M. Since then has been awake, *scratching* off the effects of the opium. Has vomited again during the last hour, and is very thirsty. She will be more careful in regulating the future use of her *nervine*, and imagines it hasn't been so big a storm after all.

Will be up and about to-day. Was giving directions to have her "paper" brought over. I am firmly persuaded that but for the antidotal effects of the atropine the patient would have succumbed to the narcotic effects of the morphine in less than an hour after I first saw her.

H. C. May, M.D.

Corning, N. Y., April 26, 1870.

Medical Items and News.

Rokitansky.—The eminent pathologist, Rokitansky, has been elected President of the Imperial Academy of Science at Vienna.

A very Old Woman.—In the town of Killingly, Conn., Mrs. J. P. Plank still lives, at the ripe age of 105 years.

Case of Trance.—A remarkable case of this character has just occurred in Newcastle. Recently the wife of a blacksmith, who had been ill for a short time, was supposed to have died, and a coffin was procured. As the lid was being screwed down the body was noticed to move, and the woman was saved from being buried alive.—*London Med. Mirror.*

Medical "Wrinkles."—The quaint and practical Thomas Inman, M.D., of Liverpool, in one of his readable essays on the "Restoration of Health," thus remarks: "Do you wish to ascertain the health of a baby, feel the condition of its buttocks. If these are firm and elastic, one may always be sure that the little one is strong and well; but if, on the other hand, they are soft, as if they were boiled turnips in a bladder, it is certain that the child is out of sorts."

Death in Forty Hours from Scarlatina.—Dr. J. J. Thompson, an English regimental surgeon, stationed at Warley, relates the case of a young recruit, with

malignant scarlet fever, admitted into hospital in the evening, having attended drill in the morning, on account of a very sore throat and high pulse. He died within 40 hours.

TETANUS PRODUCED BY THE ADMINISTRATION OF QUINIA HYPODERMICALLY.—A case of this character is reported by E. Paul Sale, M.D., Aberdeen, Miss., in the *N. O. Jour. of Medicine*. The patient, aged nineteen, mother of twins, æt. three months, was suffering from *malarial coma*, the result of a tertian intermittent fever of two months' duration. Desiring to rapidly quininize her, he administered in the arm, by hypodermic injection, quinia, gr. vj., of an ethereal solution.

Four days afterwards the arm was much tumefied, hot, and very painful to the touch, when the syringe was inserted. Twelve days from the injection, Dr. Sale was summoned to the patient's bedside to prescribe for trismus with opisthotonos; but she succumbed after receiving the best of treatment. The chief point developed by this case is this: It shows the deleterious effects which frequently follow the use of quinine hypodermically. This is the fourth case out of ten in which he has had cause to regret resorting to this method of medication, on account of the violent inflammation which has been the sequence.

A CASE OF SCHERODERMA OR SCLEREMA.—W. De F. Day, M.D., of New York (*Am. Jour. Med. Sciences*), reports a fatal case of this disease occurring in a male, æt. 37. The first case was observed by Curzio, in 1755. The present one makes the forty-fourth recorded, and the autopsy the seventh. It is a disease of middle life. In thirty-nine cases it has occurred twenty-four times between the ages of eighteen and thirty-five years. As to sex, out of forty-four cases, thirty-one have been women and thirteen men.

A NEW HAMPSHIRE PHYSICIAN MULCTED.—Dr. Greenleaf C. Clough, of Greenland, N. H. (*Medical and Surgical Reporter*), a few days since paid the sum of $1,000 for malpractice in setting a leg.

DEATH OF THE HEAVIEST WOMAN IN NEW ENGLAND.—Mrs. Susan Brown, of Monroe, N. H., weighing 500 pounds, died a short time ago, aged 75 years.

AVERAGE DURATION OF LIFE.—Dr. Pavy, the noted London physician, states that the average duration of life among the Jews is 37 years, while among Gentiles it is only 26.

SPOTTED FEVER IN GEORGIA.—One hundred and fifteen persons died with cerebro-spinal meningitis in Coffee county, Ga., in the month of March.

Malignant epidemics of this disease are prevailing, besides, in parts of Mississippi, Florida, South Carolina, and Pennsylvania.

A NEW INSECT DISCOVERED.—A New York correspondent of the *Medical and Surgical Reporter* informs us that Professor Samuel Jackson, of the Microscopical Society of New York, exhibited a new insect, called the *Tingis arcuata*, which he found up the Hudson, on the buttonwood tree. Under the microscope it is a fierce-looking animal.

A NEW WESTERN MEDICAL JOURNAL.—A creditable medical journal has recently been started by the Faculty of the Medical Department of the University of Michigan, Ann Arbor, entitled *Michigan University Medical Journal*. The April number contains creditable papers on "Sympathy," by A. B. Palmer, M.D.; "Pharmaceutical Chemistry," by A. B. Prescott, M.D.; and "Fracture of the Parietal Bone and Base of the Skull," by S. W. Davis, M.D., with comments by A. B. Crosby, M.D.

PHYSICIANS AND DRUGGISTS IN AMERICA.—Dr. A. B. Prescott, of Ann Arbor, Michigan, states that there were 55,000 physicians in this country at the last census, and 11,000 druggists. At present there are about 74,000 physicians.

THE TREPHINE.—Professor A. B. Crosby, M.D. (*Michigan University Medical Journal*), while alluding to a case of fracture of the parietal bone and base of the skull which terminated favorably, remarks:—"It is by no means certain that we might not say of the trephine, as Holmes once said of calomel, that if it were 'cast into the sea it would be all the better for men, and all the worse for fishes.' Certain it is that the trephine should only be employed as a *dernier ressort*."

THE SICK.—There are in the United States 1,360,000 "constantly sick," or twenty-four to each physician.

In the United States Army, one medical officer is provided to 333 men in regiments.

THE MANUFACTURE OF GLYCERINE IN CINCINNATI.—According to the *Cincinnati Lancet and Observer*, W. J. M. Gordon, a practical chemist of Cincinnati, makes a superior quality of glycerine in his extensive laboratory. Twenty thousand dollars a year are paid out to one house in that city for refuse material for the manufacture of glycerine, which formerly went out into the city sewers. So much for utilizing the waste products.

A NEW MEDICAL JOURNAL.—A medical journal for the practitioners of the State of Georgia will soon be brought out at Atlanta, by Dr. Love, of Albany, Ga.

THE FRUITS OF THE PUBLICATION OF MEDICAL CASES.—The *Lancet* asserts that Elliotson, in consequence of the cases he sent them in one year, passed from five hundred to five thousand a year. Professor Owen was brought into reputation by his first surgical paper respecting a particular aneurism.

A DESCRIPTION OF GOUT.—A Frenchman has thus described this affection:—"Place your joint in a vice and screw it up until you can endure it no longer. That may represent rheumatism. Then give the instrument another twist, and you will obtain a notion of the gout."

A CHAIR OF THE HISTORY OF MEDICINE.—The late M. Salmon de Champotran, of the Council of State, Paris, left to the Faculty of Medicine of Paris a legacy to found a chair of the history of medicine. M. Bouchut is the prominent candidate.

INJECTIONS IN DYSENTERY.—W. H. Davis, M.D., Springfield, Ill. (*Chicago Medical Times*), advocates, when there is a great tendency to putrescence, an injection composed of creasote ʒ j. to a pint of starch water, injected in large quantities.

MUSK IN HICCOUGH.—J. E. O'Brien, M.D., Phillipsburgh, N. J. (*The Chicago Medical Journal*), relates a case of hiccough, occurring in an erysipelatous patient, in which *musk* was successfully given to stop it, and prevent death from exhaustion. He remarks that it is very difficult to get pure musk, but succeeded in obtaining from the old drug-house of W. H. Schieffelin & Co. two fine specimens of the glands from Moschus moschiferus, containing about ʒ ij. of powder each; price $18.40. From January 21st to 28th the man hiccoughed almost constantly; after the latter date he gradually gained strength, and February 20th was able to walk about. Drs. Cavenagh and Field, of Easton, and O'Brien, are satisfied that pure musk saved the patient.

THE SOCIETY FOR THE PROTECTION OF INFANTS.—This Society held an enthusiastic meeting at Paris, Jan. 23d, 1870. Dr. Boudet was elected President, and Dr. Mayer, Secretary. It has 973 members, and 327 medical inspectors.

MEDICAL LISTENERS IN VIENNA.—Professors Hyrtl and Brucke, of Vienna University, have each from three hundred to five hundred listeners, and only seats for half that number. The Government, however, was severely taxed to build new palatial barracks for soldiers, and to pay the expenses of the king's journey to Egypt, etc., and could not erect a new university, therefore the number must be diminished.

HOW ABSCESSES ARE MANAGED IN VIENNA.—According to the Vienna correspondent of the *Chicago Med. Examiner*, opening abscesses and buboes under water, and applying plaster of Paris, is being tried here with quite satisfactory results.

THE FORM OF NOURISHMENT IN INFANTILE DYSPEPSIA.—Dr. Eustace Smith, of London (*Am. Journ. Obstetrics*), recommends as a good food, in cases where a return to the breast is impracticable, whey, made fresh as required by adding prepared rennet to cow's milk in the proportion of a teaspoonful to the pint. To two tablespoonfuls of the whey add one tablespoonful of fresh cream, and dilute with two tablespoonfuls of hot water. Of this food small quantities can be given at regular intervals, and care must be taken that it be either hot or cold, but not tepid, as liquid food given in a lukewarm state would be apt to favor a return of the vomiting. Liebig's food for infants, carefully prepared with freely diluted cow's milk, will often be borne; but in very bad cases it is inferior to the diet just alluded to. In addition, the waning powers of life must be supported by five-drop doses of pale brandy, given in a teaspoonful of the food every hour, or even oftener.

EXAMINATION OF THE URINE IN CASES OF PUERPERAL CONVULSIONS.—Prof. George T. Elliott, M.D. (*Am. Journ. Obstetrics*), advises practitioners, in an interesting and practical clinical lecture on "Puerperal Convulsions," to carefully examine the urine, so as to ascertain whether the kidneys are doing their work. Drawing it off with the catheter for twenty-four hours is the only way to be absolutely sure; then measure the amount, to know how much is passed; examine the residuum with the microscope, testing it as it comes for albumen, and then making a quantitative analysis for the urea that is being excreted. When the amount of urea comes to the full normal standard, and all other conditions correspond, the kidneys may be considered as doing their work.

AN ENDOWMENT TO THE ALBANY MEDICAL COLLEGE.—Dr. Thomas C. Durant has presented this Institution an endowment of $15,000.

AKAZGIA—A NEW ALKALOID.—At a recent meeting of the Polytechnic Association of the American Institute was described a new alkaloid found by Dr. Frazer, of Edinburgh, in specimens of the Akazgia plant brought from the west coast of Africa, and which he supposed to be a new species of Strychnos. Akazgia is a crystalline alkaloid closely resembling strychnia, but differing from it by being precipitated by alkaline bicarbonates.

THE GLYCOGENIC FUNCTION OF THE LIVER FIRST ANNOUNCED.—In 1849, M. Claude Bernard first described this important function of the organ, by the name of the "glycogenic function of the liver."

THE DISCOVERER OF THE OVULAR THEORY.—M. Pouchet, Professor of Zoology in Rouen, in 1842, first published his monograph entitled "Théorie Positive de la Fécundation," in which the discovery of the ovular theory was announced.

SOME OF THE POPULAR THERAPEUTIC AGENTS.—Edward Montgomery, M.D., St. Louis, Mo. (*St. Louis Med. and Surg. Journal*), while discoursing on the "Rise and Fall in Popular Favor of some Drugs," remarks, that it is rather strange that most of the therapeutic agents now so popular and in most constant use are of recent origin. The cinchona tree, from which is taken the Peruvian Bark, was only brought into notice as a medicinal agent in the early part of the seventeenth century, and first prominently introduced into medical practice in France by Sir John Talbot, in 1679. Dr. Duncan, author of the *Edinburgh Dispensatory*, first detected the feasibility of isolating and extracting the active principle of the bark as early as 1803, but it was not until 1820 that Pelletier and Caventon published their success in obtaining the alkaloids cinchonine and quinine. Iodine was not discovered until 1811, when M. Courtois, a chemical manufacturer of Paris, gave this valuable preparation to the world. It is only forty-three years since M. Ballard, of Montpellier, discovered in the crystallizable residue of sea water (bittern) that now popular chemical called bromine.

MILLINGER'S TREATMENT OF CHRONIC OTORRHŒA.—N. C. Washington, M.D. (of St. Louis), Vienna, Austria (*The St. Louis Med. and Surg. Journal*), calls the attention of the profession to the following method of treatment, first introduced into practice in Vienna by Dr. Edwin Millinger, clinical assistant to Professor Politzer. The method consists, first, in insuring the passage of air into the tympanic cavity by the ordinary methods. The Eustachian catheter is then introduced, and firmly fixed in position. Then, with a syringe adapted to the catheter, tepid water is passed carefully through it. The pus is thus made to pass partly out through the perforated membrana tympani, and partly into the pharynx, by the side of the catheter. After thus literally bathing the diseased surfaces, a weak disinfecting solution of hypochlorite of soda is injected, to be followed by a weak astringent solution, either zinc or silver. Solutions of sulphate of zinc or nitrate of silver are the best astringents for use in the manner described, and for instillation into the external meatus. The relief from pain is almost immediate, the cure speedy and permanent. The theory of the treatment lies in the principle of securing perfect cleanliness.

Lecture II.

Physical Diagnosis of the Diseases of the Cerebro-spinal Axis—(A) Perversions of Contactile Sensibility—Æsthesiometry—Relative Estimate of Weight—The Muscular Sense—(B) Perversions of Temperature—(C) Perversions of Muscular Power—Dynamometry—(D) Structural Perversions of the Optic Disc—Cerebroscopy—(E) Diagnostic Value of Electricity.

The diagnosis of many of the disorders of the nervous system may be greatly helped by investigating conditions suspected to be present by means of certain instruments of precision. By their intelligent use we find out the relation of the observed phenomena to given morbid states of the brain and spinal cord, and fix their symptomatic worth. This constitutes the

PHYSICAL DIAGNOSIS

of the diseases of the cerebro-spinal axis. The conditions to be especially noted are, perversions of function in the skin and muscles, altered thermal conditions in certain districts of the body, and changes in the blood-vessels and in the nutrition of the interior of the eye, particularly of the optic disc. These may be considered under the several heads of: (*A.*) Perversions of Contactile Discrimination, used preferably to Weber's term "tactile sense;" (*B.*) Perversions of Temperature; (*C.*) Perversions of Muscular Power; and (*D.*) Structural Perversions in the sight-organ or eye.

(*A.*) Two kinds of sensibility exist in the skin and in the mucous membranes around the natural orifices. The one is ordinary tactile sensibility, or the sense of touch, which, exercised in its simplest form, gives the idea of resistance, and, in connection with the so-called muscular sense, enables us to judge of the characters of external bodies, as their smoothness of surface and their form; and the other is the sense of pain, including the appreciation of heat and burning. The skin may lose the sense of pain without tactile sensibility being modified. Gentle rubbing of the finger over the skin may be felt, whilst there is total insensibility to pricking and pinching, and burning; but the converse is not true, for when contactile discrimination is lost, the sense of pain is always wanting. The sensation of tickling is included under the head of tactile sensibility.

The modifications of contactile discrimination are (*a*) increase—*hyperæsthesia;* (*b*) diminution or loss—*anæsthesia;* and (*c*) retardation in the transmittal of the impression—*dysæsthesia*, or *bradyæsthesia*. The loss of the sense of pain is *analgesia*.

The perfectness of the sense of contactile discrimination depends on the integrity of three concurrent factors: namely, (1) the sensitive nerve-extremities to which the stimulus is applied; (2) the afferent nerve-fibres which carry the impression to the centre; and (3) the centre which may receive the impression and transform it into a sensation. If any one of these is damaged, diminution or loss of sensation must follow. If the centre cannot receive and act upon the transmitted impression, there can be no sensation. If the nerve-fibre is injured to an extent to destroy its conducting ability the impression cannot be sent inwards, and consequently be perceived.

We are able to measure more or less accurately the degree of contactile discrimination by applying the results of the observations of Professor Ernest H. Weber, which show the discriminative faculty which the skin possesses of recognizing double impressions made upon it within a given limit, but varying in different parts of the body. This has been called the "sense of 'space' or locality." His mode of ascertaining this was to touch the surface with a pair of mathematical compasses, whose points were covered with pieces of cork, and then, the eyes being closed, their legs were brought towards each other, until they were at the smallest distance they could be felt as two bodies, called by Dr. Graves "the limit of confusion." Weber found the extremes to vary from half a line on the point of the tongue to thirty lines in the skin of the back and the middle of the thigh. A series of similar experiments were reported by Dr. Ballard in the *Lancet*, 1862, vol. i., p. 303, in which he found in the hand the tip of the index finger was the most, and the dorsal surface of the base of the fifth metacarpal bone the least, sensitive part; the "limit of confusion" in the former being 0·35 of a line, and in the latter 5 lines. The parts in which the sense of touch is least acute are, the neck, the middle of the back, the middle of the arm, and the middle of the thigh; the other parts of the body possessing various intermediate degrees of sensibility. At the tips of the fingers and the point of the tongue it can be distinguished most readily in the longitudinal direction; whilst on the dorsum of the tongue, the face, neck, and extremities, the discrimination is more delicate with the points placed transversely. As a general rule, it would seem that the sensibility of the trunk is greater on the median line, both before and behind, and less at the sides. But subsequent observations have shown that there is much individual variation in the "limit of confusion," some persons in a perfectly healthy state, as regards their nervous system, being able to distinguish the points at one-half or even one-third of the distances that can be done by others. Czermak has shown that two points may be brought together much more nearly, and yet be distinguished as two, when applied one after the other, and not at the same time. The delicacy of the perception would seem to be blunted if the skin be either artificially or naturally stretched. I refer you to the various works on Physiology for the tables of Weber and others, giving the tabular results, with the maxima and the minima.

Weber's physiological observations were first applied clinically, as a method of detecting and measuring the modifications of contactile sensibility in the diseases of the nervous system, by Dr. Brown-Séquard, in 1849, and called *Æsthesiometry*. He claims by the aid of this method, that: (*a*) any slight increase or decrease of contactile sensibility may be readily recognized, which may not be discoverable by any other means; (*b*) the degree of increase or decrease may be exactly measured; and (*c*) changes in the degree of existing hyperæsthesia or anæsthesia may be accurately ascertained. He first used a pair of common compasses, as found in any mathematical instrument case; but in 1858 he had made an ingenious instrument, which is in general use, and called an æsthesiometer (Fig. 9). It is a decimetrical rule, much like a shoemaker's measure, and graduated to millimetres. At one end is a fixed

branch; another similar one slides on the rule, marking the distances at which the points begin to be felt when

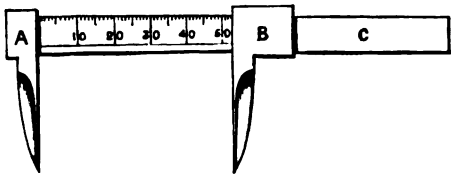

Fig. 9.—Æsthesiometer of Brown-Séquard.

applied to the skin. When used, it is held on its flat sides, near its centre of gravity, by the thumb and three last fingers, whilst the index, slightly bearing on the back of the rule, regulates the contact of the points with the skin, which must be in exact parallelism to the surface. About the same time Dr. Sieveking, of London, devised an instrument on the same principle, but with a shorter handle. Later (1859) Dr. John W. Ogle, of London, believing that an instrument which combined the principle of the beam compass with that of the two-legged, proposed his *aphemetric compass*. Messrs. G. Tiemann & Co., of New York, have made a convenient æsthesiometer by adding a brass scale to one of the limbs of the ordinary mathematical compass. Its fault is its unnecessary length (Fig. 10). The in-

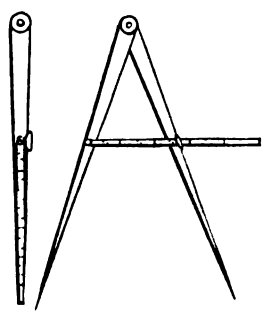

Fig. 10.

strument I prefer is the one made for Dr. Jaccoud by Robert and Collin, surgical cutlers, of Paris. It is nine centimetres long, is provided with a movable scale in the form of an arc of a circle, and folds up in a small space, so as to be easily carried.

Dr. Brown-Séquard remarks in his excellent article on Æsthesiometry in the *Dictionnaire Encyclopédique des Sciences Médicales*, t. 2ième, that for those who treat nervous diseases the æsthesiometer is as indispensable as is the stethoscope for those who treat diseases of the heart; and there is no doubt that, when understandingly used, it not only measures with great nicety the degree of contactile discrimination, and thus ascertains its perversions, but often aids us in making out the precise site and nature of the disorder, particularly if the disease be at the base of the brain, or in the spinal cord. In many instances where the ordinary methods show no loss of sensibility, æsthesiometry will demonstrate that it is notably impaired.

In practising æsthesiometry the following rules should be closely observed. 1. The points of the instrument should be covered with bits of cork, for the slightest prick will interfere with the accuracy of the perception of the impression. 2. The points must be exactly and simultaneously applied. 3. The patient should not see the application of the instrument, although his attention should be alert, nor should he be told beforehand the precise bearing of the experiment. To try accurately the degree of his "sense of space," it may indeed be proper to let him sometimes suppose that only one point is applied, or again both points, when the reverse is the case, to guard against the effects of the imagination. In such cases one point only may be applied, and then, after the patient has asserted that he feels both, let him be convinced that only one has been used, so that a right conclusion may be had as to whether the patient judges by his sensations or by a preformed notion.

You have been already told that the natural distance-limit, the "limit of confusion," is not the same in all parts of the body, but it usually does not vary in the same district in different persons. The normal distance-limit is the same, or nearly so, in corresponding parts on the right and left halves of the body. Before beginning an investigation of the degree of tactile discrimination in the parts where some modification is suspected, the æsthesiometer should be applied over a healthy portion of the skin, the two points being so arranged that the impression of one and two points can each be felt. The instrument should then be changed to the part whose tactile sensibility is to be explored, and the two points applied at the known normal distance-limit; if one point only is felt the instrument is lifted off, and the two points are gradually separated from each other and reapplied, until both are felt. Both the existence and the amount of anæsthesia are thus known and measured. If the two points are felt at the normal distance-limit they are gradually brought together, and their application repeated until there is a sensation of only one point. In this way we measure the degree of hyperæsthesia. The æsthesiometer should not immediately be reapplied upon the same point of the skin, for the feeling of contact often lasts for half a minute, and thus, after one or two applications, two points may be felt instead of one. Where the perversion of tactile sensibility is limited to a very small area, a half minute should elapse before the instrument is reapplied.

Where the anæsthesia is of some extent, the two points may be applied one after the other, with intervals of forty or fifty seconds, and yet give the sensation of only one point; this is due to the slowness of the transmission of the impression—dysæsthesia or bradyæsthesia. The æsthesiometer here will measure the *rapidity of the transmission of tactile impressions*, and this is of grea timportance in some affections of the cord, as, for example, locomotor ataxy.

When a great degree of anæsthesia exists, the two points of the æsthesiometer are felt only as one, no matter how large the space between them, always provided that they are applied upon the same longitudinal line. Brown-Séquard mentions an instance where one point was placed on the wrist and the other well up on the forearm, and yet there was a sensation of one point only.

But the degree of hyperæsthesia may be such, that, no matter how close the two points may be, both continue to be felt. In a case of chronic spinal meningitis, tactile sensibility was so much heightened that the patient felt both points applied to the thigh at a distance of one millimetre apart, whereas the limit of confusion was five or six.

When the patient is taking either strychnia or belladonna, it should be borne in mind that both drugs modify the sense of space, the former increasing and the latter lessening it; therefore, in such cases explore first

very carefully the healthy portions, and establish the actual normal type.

In certain cases, when two points of an æsthesiometer are applied, a distinct sensation of three points is felt; or two points are felt when one is applied; this condition is connected with disease of the base of the brain, and its sites are the face, neck, and hand, but especially the face. Some interesting instances are mentioned by Dr. Brown-Séquard (*Archives de Physiologie*, année 1868, t. 1er), as when the distance between the two points of the instrument was two centimetres, two, or sometimes but one, point was felt; but at two and a half or three, or even at four centimetres, there was a distinct sensation of three points.

In connection with contactile discrimination we may also study the relative *appreciation of weight* or *pressure* when applied to the surface, the part experimented on being supported, as when the hand is laid upon a table. Aubert and Kammler found that on the face and back of the hand, the pressure of a square piece of elder pith, with a surface of nearly one-third of an inch, and weighing one-thirty-third of a grain, could be differentiated; whilst the tips of the fingers required a weight, of the same superficies, of one-third of a grain heavier, and the toes as much as eight grains, before the sensation of pressure was made. The appreciation is nicer if the bodies are successively applied at intervals of a few seconds. In Weber's experiments, when 4 and 5 ounces were applied one after the other, an accurate judgment of the difference could be made after ninety seconds; but that between 14·5 ounces and 15 could not be accurately discriminated after forty seconds.

But this relative estimate of weight, when assisted by the so-called muscular sense, is, as Weber first proved by his interesting experiments, far more delicate than by the bare sense of pressure, for a difference between two weights may be detected when one is only one-twentieth or one-fifteenth less than the other. Smaller differences are perceived when light weights are used. Ounce weights are distinguishable in the ratio of 29 to 30, and with drachms the same ratio holds, so that the addition or removal of one drachm to a weight of 30 drachms will be felt. Now, in some of the affections to be considered, this can be utilized clinically, as we shall see later in the course. Dr. Jaccoud has shown that in the lower extremities this faculty of differentiation is much less than in the upper, and that for accurate distinction a difference of from 12 to 16 troy ounces is necessary. His method of practically applying this method of investigation is by means of an apparatus consisting of two square bags, open at one end, to which a cord is fastened as about the mouth of a purse, which secures them on the limb. The test weights, one heavier than the other, are put in the bags; the patient, with his eyes bandaged, is placed in the horizontal position, so that the lower limbs extend beyond the edges of the bed or table on which he is lying, and are unsupported; or he can be laid across the bed, or on a sofa, and the legs held up by an assistant. The bag containing the lightest weight is then fastened around the ankle, so that the instrument will not slip up the leg when the latter is raised. He is then made to lift the limb, and to keep it so for several seconds, until indeed the idea of the weight is fully perceived; it is then replaced in its former position. As soon as practicable the heavier weight is substituted, and the same procedure is repeated. If the so-called muscular sense is intact, the difference of weight is appreciated by the amount of effort the patient is required to make to raise and support it when the limb is in direct extension. When this sense is lessened or gone, it becomes necessary to more or less balance the weights before the differentiation is made; and not infrequently the appreciation is directly the contrary of the fact, the heaviest weight being judged the lightest. A rougher but speedier method is to attach the two bags each to a foot at the same time, and then make the patient raise both legs at once; when muscular anæsthesia exists no difference is appreciated, unless there is a difference of from 3 to 15 ounces. In two cases of locomotor ataxy no distinction was made where the ratio was less than 1 to 100.

It may be well to allude here to the employment of one of the natural modifications of common sensibility as a means of diagnosis—the feeling of tickling, which is most readily excited in parts which have a low tactile sensibility, as the arm-pits, flanks, and soles of the feet. It is often necessary to resort to this excitation to discover both the state of sensibility and conduction, and of reflex action.

(*B.*) The *local perversions of body-heat* in many disorders of the brain and cord have been studied only of late years. It is important that in all of them the local and general temperature should be noted. In most cases of recent hemiplegia the temperature of the palsied side is raised from a few tenths of a degree to one degree; it is rarely natural, but is sometimes lessened. The difference of temperature may be present in all cases of unilateral palsy symptomatic of various centric lesions, as hemorrhage, softening, &c. Whatever part of the brain is damaged, this increase is generally to be noted: but it has not yet been decided what relation the disturbance bears to the site of the lesion. After cure the equilibrium is restored, but the duration of the unilateral rise of temperature greatly varies in different cases, in some persisting for years, whilst in others it may not last longer than a couple of months. But even in long-standing cases a time comes when there is thermic equality, and Dr. Folet, who has particularly studied this subject, thinks this happens at the beginning of the consecutive atrophy. When after a long continued hemiplegia, with persistent excess of body-heat, the other side becomes palsied, either the temperature of both sides is equal, or the difference, when existing, is to the credit of the side last affected. The temperature of the affected parts does not appear to be influenced by the presence of muscular rigidity. The general body-heat of hemiplegic patients does not seem to be increased as a rule. In immediately fatal cases of unilateral cerebral paralysis following either hemorrhage or softening, Dr. Charcot and his pupils have made out three thermic periods—(1) A fall of about 1° Fahr.; (2) Oscillations between the normal temperature and 100° Fahr.; and then (3) a rapid rise to 105° Fahr. and upwards immediately before death. In the palsies dependent on disease of the spinal cord, or of the spinal nerves, or connected with nutritional errors bringing on muscular atrophy, there is always a reduction of temperature in the affected parts, and in some cases a return to the natural standard is among the first evidences of improvement.

In most cases the thermometer will detect the variations of temperature, and is the only instrument needed. But where the variations are very slight they can be best discriminated and most accurately measured by means of Becquerel's discs, in connection with a galvanometer. These are two thin plates of copper, of the size of a half-dime, soldered to a thin rod of bismuth, contained in a small tube of hard rubber with a handle. One disc is placed on the sound limb and the other on the corresponding part of the

palsied limb. Both discs are in connection with the poles of a galvanometer of delicate metallic wires, covered with silk thread. If the temperature of both limbs is the same, or natural, the needle of the galvanometer does not move; but if the heat of either is raised, the deflection of the needle is to the north or south pole, according as one or the other limb has the highest temperature.

In studying the *perversions of muscular power* we should bear in mind that muscle is the instrument and not the producer of force, the genetic factors being in the gray substance,—the nerve-centres,—the libero-motor system. Hence damage to these centres is followed by derangement of muscular function—diminished or total loss of motor power being one of the most frequent consequences of lesions of the brain and cord.

When we want to learn the degree of strength in the muscles of the arm, when paretic or palsied, the habit generally is to make the patient grasp the physician's hand; he is told to squeeze it, &c. This is a very rough, and in many ways a very unsatisfactory, method, and does not serve to indicate the changes for better or for worse in the progress of the palsy. To measure accurately the energy of muscular contraction in the upper extremities, several instruments have been invented. The one I show you is a simple and useful one; it is known as the dynamometer of Mathieu, a surgical cutler of Paris. (Fig. 11.)

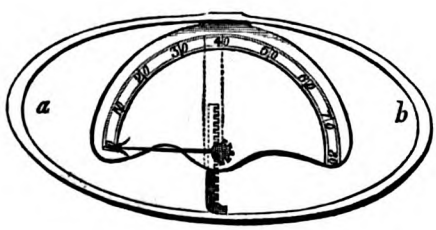

FIG. 11.—Dynamometer of Mathieu.

There is an elliptical steel spring, within and attached to which is a brass semi-circle with a scale; a steel arm, one side of which is cogged, moves an indicator, with a small cog-wheel attached, around the brass arc. The lower end of the arm rests on the elliptical spring when the indicator stands at zero on the scale; a brass sheet on the under side of the scale keeps this arm in place, but at the same time not hindering its movements. By squeezing the instrument the tendency is to bring together the two sides of the ellipse, and the steel arm, being shoved up by the lower side of the spring, causes the indicator to move forward. On the pressure ceasing, the indicator does not return to the starting-point, 0, but remains at the point to which it may have been carried by the muscular action of the patient, and thus it measures its degree. The pressure is made in four ways: (*a*) suddenly, and with all the will of the patient; (*b*) steadily, with gradual increase of will, or the reverse; (*c*) alternately, with strong and feeble strength; and (*d*) pressure at the word given, so as to measure the time taken by the will to reach the contractile muscle. It may also be used to measure tactile force, by fastening to the spring at the points *a* and *b* two hooks, with cords attached; traction on the cords will tend to approximate the sides of the instrument, and by pushing the steel arm move the indicator.

Professor W. A. Hammond states that he has found Mathieu's dynamometer useful in determining the effect of electricity on the irritability of palsied muscles, and thus enabling the physician to decide upon the appropriate time to employ it, by noting whether muscular strength is increased or diminished after its use.

D. Since the discovery of the ophthalmoscope, the connection of the interior structures of the eye with diseases of the nervous centres has been made apparent. The importance of *ophthalmoscopic exploration* of the inner eye, when practicable, in all cases of acute and chronic disease of the cerebro-spinal axis, as an aid to diagnosis, is now universally recognized; and this should be done whether there is any complaint of defect of sight or not. The changes in the inner eye which accompany certain affections of the brain and spinal cord happen in the optic disc, in the choroid, and their vessels. The optic disc may become congested or anæmic, or nutritional tissue-changes may occur, ending in atrophy. I shall only generally indicate some of the disorders of the cerebro-spinal system in which functional and structural perversions of the inner-eye structures may take place, and which are made manifest by *cerebroscopy*. I can do this best by summarizing the results of Dr. Bouchut's observations, who was among the first, if not the first, to develop this element of the physical diagnosis of diseases of the nervous system. 1. Optic neuritis and neuro-retinitis, choroiditis, and atrophy of the discs, are present in most acute and chronic affections of the brain and spinal cord. 2. The law of coincidence of optic neuritis and organic lesions of the nervous system may be explained by the anatomical and physiological relations of the eye with the brain and spinal cord. 3. Whenever any positive hindrance happens in the cerebral circulation, as a consequence of some lesion of the brain or cord, there is papillary and retinal hyperæmia. 4. When there is acute or chronic inflammation of the brain, it may extend to the eye by following the course of the optic nerve. 5. Affections of the anterior columns of the cord may, by reason of the anastomosis of its nerves with the sympathetic, at the level of the two first pairs of dorsal nerves, induce papillary hypertrophy with consecutive atrophy of the optic nerve. 6. Optic neuritis and neuro-retinitis from acute or chronic diseases of the nervous system are generally bilateral. 7. In affections of the brain and its meninges, optic neuritis is usually more marked in the eye corresponding to the hemisphere chiefly interested. 8. Changes in the optic disc and retina, attending disorders of motility, sensibility, and of the intellect, always indicate organic disease of the brain.

Bouchut thinks that the changes in the inner eye often occur early enough to be the first certain signs of the existing disease. He relates a case of tubercular meningitis of the surface of the brain, in which the diagnosis by the rational symptoms was at first doubtful, but which was at once made clear by the ophthalmoscopic signs. Intra-cranial tumors, including all enlargements and thickenings from any cause, are a frequent cause of ischæmia and neuritis. When the cerebellum is damaged the optic discs are affected. Acute and chronic cerebritic softening alone never causes ischæmia, the changes being neuritis and atrophy. In cerebral hemorrhage, when the effusion is large, there is stasis and infiltration in and around the discs, caused mechanically by the obstruction, and this is most marked in the eye on the side of the clot. In symptomatic epilepsy, with coarse cerebral lesion, atrophy of the disc is common, but it is never associated with essential epilepsy. Some circulatory troubles, as venous dilatations in some cases, are met with. Dr. Hughlings-Jackson has recorded many instances of

convulsions beginning unilaterally, in which there was double optic neuritis. In general paralysis, atrophy of the discs is nearly a constant, though rarely an early, symptom, happening usually towards the end of the first or the beginning of the second stage. In the several sclerotic diseases of the spinal cord—as locomotor ataxy, multiple or disseminated sclerosis of the cord, &c.—it is not infrequent, as we shall see when we come to study those affections.

E. In conclusion, I will make brief mention of

ELECTRICITY

as an auxiliary means of diagnosis in paralytic affections. Marshall Hall first directed attention to the diacritic value of galvanism and faradism in the several forms of palsy. By them we can determine the degree of muscular irritability and contractility, and of cutaneous sensibility; and here, I think, we have the whole present worth of electricity as a diagnostic help in the palsies. The field is a large one, and may be yet more profitably cultivated.

It had long been noticed that muscles which did not answer to the will, would quickly and even forcibly act under the influence of the electric current, whilst in other instances the contractions of palsied muscles were feeble or wanting when the same stimulus was applied. And we put these facts to diagnostic use by testing the degree of *electro-muscular irritability* and *electro-muscular contractility* present in a given case. By electro-muscular irritability we measure the quality of the existing irritability of the muscle-fibres, by seeing how quickly they answer to the lowest electrical power; and the lower the power and the sooner the comparative response—the muscles of different limbs, or different groups of muscles being experimented on—the greater the irritability of that muscle or set of muscles. This readiness of contraction should not be mistaken for energy of contraction, or electro-muscular contractility, which tokens the amount of muscular force. When you test for irritability a weak current is used—the weakest that will produce any effect; when you are trying contractility or power, a much stronger current will be necessary. A palsied muscle may be more irritable than a sound one, and the former will respond to a current that will have no effect on the latter; whilst a strong current may cause violent contractions of the healthy muscles, and scarcely perceptible ones of the damaged muscles.

In this lecture time will not allow me to even hurriedly indicate the several conditions of the nervous centres which may be associated with the various degrees of electro-muscular irritability and contractility. In treating of the special palsies I shall have occasion to refer to these diagnostic tests, and clinically apply them, and point out more in detail the principles which guide their practical use. Before quitting the subject at this time, I will, however, state that electricity is a precious help in making out the site of the lesion causing the loss of volitional power over the affected muscles. The fault may be somewhere in the course of the nerve, that is, between its offstart at the cord and its peripheral termination, by which its tissue is damaged, and its faculty of conductibility is lessened or destroyed. The nerve-fibres may be cut or torn across, or bruised, or some morbid growth, as a neuroma or other tumor, may exist upon it, or near it, pressing upon it, and functionally hurting it. Here electro-muscular contractility will be diminished in the muscles which the compromised nerve supplies, just in proportion to the amount of injury; and the response to the electric stimulus be proportionally slight or absent. Or there may be disease of the cord at the point of emergence of the nerves going to the palsied muscles; in this case the same state of things will be present. But suppose that the damage to the cord is above the segment from which the nerves of the palsied limbs are given off; then electro-muscular contractility may be preserved, though the action of the will is paralyzed as to those muscles, for they are cut off from all communication with the great centre of volition, the cerebral hemispheres. Again, some of the brain-ganglia may be damaged, and the producing centres be at fault,—causing cerebral paralysis; the palsied muscles will here reply more or less promptly and powerfully to the electric excitation, except in those cases in which there are secondary descending lesions of the cord; and this very important question, in a prognostic point of view, we are often enabled to make out by the electrical test. Lastly, the muscles themselves may be primarily affected, and be the seat of progressive tissue-changes, causing functional incompetency. We shall see a whole and important class of palsies in which the apparent coarse lesion is in the muscular structure. By galvanism and faradism we can also often decide whether the weakened condition of the muscle is due to functional disuse, or to persisting central mischief.

By electricity the physician can detect and expose imposture in cases of malingering, both in civil and military life, where palsy is feigned either for purposes of personal advantage, as after railway accidents, or to shun duty. In so-called hysterical paralysis it is a great help in fixing the "sham."

Finally, electricity informs us of the state of cutaneous sensibility, and gives us measurable periods of the transmission of peripheral impressions to the perceptive centres.

CAUSES AND ANATOMICAL CHARACTERS OF TUBERCULOSIS IN INFANCY AND CHILDHOOD.

By J. LEWIS SMITH, M.D.,

NEW YORK.

(Read before the N. Y. Medical Journal Association.)

TUBERCULOSIS occurs at any period of life. It is indeed more frequent in early manhood than previously; but it presents peculiar features in children, and especially in infants. Like most other general diseases, tuberculosis has a local manifestation which serves for diagnosis. This is a small, round, nearly transparent granulation, designated tubercle, which is developed within a tissue, or upon its surface. In certain situations it departs from its typical rounded form, and is more or less flattened. It is firm to the feel, and, when fully developed, varies in size from a pin's head to a small pea. It has recently, in its various phases, been studied with great interest by pathologists in Europe, and to a certain extent in this country, and these investigations have already thrown considerable additional light on the nature of tuberculosis.

The statistics of tuberculosis, previously to the last ten years, were not strictly accurate, since cheesy degeneration of whatever part was regarded by most pathologists as a tubercular lesion in all cases, and its presence in the cadaver was therefore considered sufficient proof that the disease of which the patient died was tuberculosis, whereas it is now known to be in many instances a degenerated product of simple inflammation. I have records of the histories and post-mortem examinations of thirty-six cases of tuberculosis occurring under the age of five years, and I have rejected all

cases of cheesy degeneration when not accompanied by other evidence of tuberculosis. Thus, caries of the vertebræ, with cheesy substance in the bony excavations, I have not considered tubercular. I have rejected one case in which three large cheesy bronchial glands lay in front of the carious vertebræ, inasmuch as there were no tubercles in the lungs or elsewhere. In another rejected case, the only lesions were empyema of the left pleural cavity, hyperplasia, and cheesy degeneration of the bronchial glands, and a single large cheesy nodule in the right lung. This patient may or may not have had tuberculosis.

ETIOLOGY.

The tubercular diathesis may be inherited. Hence the well-known fact of tubercular families. Cases are not unfrequent in which hereditary tuberculosis proves fatal before the death of the affected parent. The offspring of a tubercular parent does not, as a rule, have tubercles at birth; but the tubercular diathesis, at first latent as in syphilis, manifests itself in a few weeks, or months, in the formation of tubercles, and in the consequent cough and emaciation. In two cases, however, in my collection, a cough was observed, according to the statement of friends, as early as the second or third week. Under good hygienic conditions the inherited diathesis may remain latent or be removed. If both parents are tubercular, the offspring almost necessarily becomes so.

Tuberculosis frequently results from prolonged anti-hygienic conditions in those previously healthy and of healthy parentage. It may result from residence in damp, dark, and dirty apartments, from scanty or unwholesome food, protracted and exhausting diseases, in fine, from any agency which gives rise to great and continued impoverishment of the blood. Age is a predisposing cause. Tuberculosis is comparatively rare under the age of one year, while it is not uncommon in wasted infants between the ages of two and five years. This remark is fully substantiated by the statistics of the Nursery and Child's Hospital and Infants' Hospital of this city.

Is tuberculosis propagated by infection? Most physicians would answer in the negative, though in some countries, as in Italy, it is stated that the profession have long regarded it as mildly infectious. Every physician of experience must have remarked the frequency with which tuberculosis occurs in those not predisposed to the disease, but who have been in intimate relation with consumptive patients. This has been commonly regarded as due in no way to infection, but has been thought to be a coincidence, or has been attributed to an influence, not fully understood, which the emotions or imagination exerts in the causation of diseases. But recent discoveries concerning the etiology of tuberculosis, which will presently be related, afford ground for the opinion which some of our best authorities in the pathology of tuberculosis, as Waldenburg, now hold, that minute particles exhaled or expectorated from the lungs may be the medium of infection.

In December, 1865, M. Villemin read before the Academy of Medicine of Paris, and published, his celebrated memoir, which contained the results of his experiments in inoculating certain lower animals with tubercular matter. Since then the fact has been established by many experiments, that tubercle may be produced in the rabbit and other animals by inserting under their skin various pathological products, whether tubercular or non-tubercular, as gray tubercles, cheesy products, thickened pus, etc., and by inserting finely divided foreign substances, not animal, as aniline blue, and also by traumatic irritations which give rise to the formation of inflammatory products under the skin, as the use of a seton. The coloring matter, whether introduced alone or in combination with a pathological substance, is found in the tubercle which results in the lungs or elsewhere. Therefore it is inferred that tubercle in these experimental cases is produced by minute particles of the inserted substance, which enter the circulation and are deposited in the lungs or other organs. Where they are deposited, inflammation, or, in the words of modern pathologists, formative irritability arises, with proliferation of the cellular elements of the part. This corpusculation produces the tubercle.

The importance of these discoveries is apparent. Cheesy substances produced in the system, whether in the lungs, lymphatic glands, bones,—as in vertebral caries,—or elsewhere, and also long-retained purulent collections, as in empyema, may give rise to tuberculosis, provided particles of the morbid substance gain admittance into the circulation. The intimate relation long observed between scrofula and tuberculosis is explained, since the former is attended by hyperplasia and cheesy degeneration of the lymphatic glands, and by slow suppurative inflammations.

Blood extravasated in the alveoli of the lungs, and undergoing degenerative changes, is considered a cause of tuberculosis; but such extravasations are rare prior to the age of puberty. Protracted inflammation of the air-passages, as bronchitis or laryngitis, is believed by some good observers to give rise to tubercles in certain cases, but the proof of this is not at all conclusive. In infancy and childhood the common cause is a diathesis inherited, or acquired through impoverishment of the blood by previous disease or anti-hygienic conditions, or it is infection of the system from cheesy glands or purulent collections.

It is my opinion, based on these recent discoveries, and the post-mortem examinations which I have made, that the immediate cause of the formation of tubercles in the lungs, spleen, and other viscera, in a considerable number of cases, is hyperplasia and cheesy degeneration of the bronchial and mesenteric glands, whether or not this glandular affection is to be considered tubercular. Thus in the two last cases which I have examined there were minute transparent tubercles in the lungs, some becoming yellow, evidently of very recent formation, and also in one of the cases in the spleen, while in both cases the bronchial glands were enlarged and cheesy, and in one also the mesenteric. In another case, occurring in the Child's Hospital, the bronchial and mesenteric glands were cheesy, with all the thoracic and abdominal viscera healthy, while there were granulations nearly the size of a pin's head, due to cell proliferation, as ascertained by the microscope (tubercular) in the pia mater at the base of the brain, along its sides, and between the hemispheres.*

The Society will pardon a brief exposé of the present views of pathologists in reference to the general anatomical characters of tuberculosis, since the pathology of this disease has recently been so thoroughly and successfully studied, especially on the continent. This will aid to a better understanding on the subject which we are to consider in this paper.

GENERAL ANATOMICAL CHARACTERS OF TUBERCULOSIS.

Analysis of the blood of tubercular patients shows an increase in the water, albumen, fats, and white corpuscles, and a decrease in the number of red corpuscles.

* In some cases long retained collections of pus appear to sustain the same causative relation to tuberculosis in childrenas do cheesy products. Since the reading of this paper I have met such a case. There were minute tubercles, evidently recent, in both lungs; no cheesy substance in the glands or elsewhere, but a large abscess in the thigh, which had been detected a month before death. The specimen was presented to the Pathological Society.

The fibrine is slightly diminished, except in cases complicated by inflammation, in which it may be in excess. The chief interest, however, as regards the anatomical characters of tuberculosis, pertains to the tubercle. The tubercle is as characteristic of tuberculosis as the eruption is of an exanthematic fever. It is produced, as already stated, by a local proliferation or corpusculation. It is therefore a cell-growth, and not a deposit.

If we examine with a microscope a thin section of a recent tubercle, we will observe in its peripheral portion, in which proliferation was active at the time of death, large mother cells, spindle-shaped fibro-plastic cells, and small round cells, which have been released from the mother cells. This zone of proliferation often has considerable extent. Passing towards the central portion of the tubercle, we find these small round cells in great abundance. They represent a more advanced stage of the tubercle, since the central part is oldest. They are the most numerous cells in the tubercle, and they have been designated the tubercle cells. They resemble closely in appearance the smaller of the white corpuscles of the blood, and cannot be distinguished from the normal cells of the lymphatic glands, each consisting of a single large nucleus surrounded by protoplasm. They are among the most fragile of pathological cells. The cells are held together by a transparent adhesive substance, which is firm and resisting.

Every tubercle tends to undergo a molecular change by which its transparance is lost. This consists in a decay of the cells and the intercellular substance. Granules of fat are deposited within them, and the cells shrivel and disintegrate. Fragments of cells, and shrunken cells, and cell-nuclei are thus produced, which Lebert described as the tubercle cells, and which were accepted as such by all observers till Virchow ascertained their true character. The molecular change which I have described commences in the interior of the tubercle, and extends outward till the whole tubercle becomes opaque and yellow, and at the same time so friable as to be readily crushed between the fingers. The yellow tubercle is therefore only an advanced stage of the gray semi-transparent.

It is evident that tubercle in its first period possesses vitality, and, like all neoplasms, has its blood-vessels. These are soon closed by coagula of granular fibrine, mixed with white blood corpuscles. When the tubercle has reached the yellow transformation, its vessels are no longer pervious, but it is surrounded by a vascular zone, in which circulation continues. The subsequent history of tubercle is well known. It is seldom, perhaps never, absorbed. It softens, and henceforth, as has been said by a German pathologist, its history is that of an abscess. It is an irritant, producing inflammation in the surrounding tissues, with thickening and induration, and abundant production of pus cells, which mingle with the tubercle elements. Ulceration and discharge of the liquefied substance upon one of the free surfaces is the common result. In exceptional cases, instead of softening, the tubercle may undergo fibroid degeneration or cretification.

ANATOMICAL CHARACTERS IN INFANCY AND CHILDHOOD.

The anatomical characters of tuberculosis in the first years of life vary in certain particulars from the form which they present in the adult, but after the age of three years the differences are fewer and less pronounced than previously.

Tubercular laryngitis, so common in the adult, is absent in a large proportion of cases under the age of three years, and when present has little intensity; and ulceration of the larynx very seldom occurs. This has been attributed to the fact that there is so little expectoration in young children, the sputum being an irritant. Niemeyer, however, does not consider the sputum of tuberculosis sufficiently irritating to cause the laryngitis and laryngeal ulceration; but the arguments in favor of this mode of causation, in my opinion, more than counterbalance those which have been presented against it.

I have never met a case of tubercular ulceration of the larynx or trachea in the post-mortem examination of young children, nor do I recollect ever treating a case in which there was that degree of dysphonia which indicated ulceration. Rilliet and Barthez, in more than 300 necropsies of tubercular cases, found no ulcers in the larynx or trachea under the age of three years; 8 cases between the ages of three and ten years, and 8 between ten and fourteen years. The ulcers, whether seated in the larynx or in the trachea, —and they are in most cases in the former, since the inequalities upon the surface of the larynx favor the retention of the sputum,—are commonly small, superficial, round or elongated, and with little thickening or inflammation of their borders. Occurring in the folds of the mucous membrane, for example, around the vocal cords, their form is usually elongated.

Bronchitis is not infrequent. This inflammation is due to, and dependent on, the pulmonary tubercles, and is therefore most intense in the part of the lung where the tubercles are most abundant and farthest advanced. It is therefore more intense on one side than on the other, and it may be unilateral. It differs in this respect from idiopathic bronchitis, which is commonly pretty uniform on the two sides. It differs also in the fact that it is sometimes accompanied by ulcerations. The ulcers are round or elongated in the direction of the axis of the tubes, and, like those of the larynx or trachea, are superficial. Idiopathic bronchitis of infancy and childhood does not cause ulceration. Circumscribed inflammation may attack a bronchial tube, as, indeed, the trachea, and give rise to ulceration and perforation, from the presence and pressure of a diseased lymphatic gland external to the tube. This subject will be treated of hereafter.

LUNGS.

It is well known that in the adult tubercles are always present in the lungs, if they occur in any part of the system. I have met two cases in the 36 post-mortem examinations of young children in which the lungs were free from tubercles and healthy. One of the two was an infant, but its exact age is not stated in the records. It had cheesy degeneration of thymus and bronchial glands, enlargement of mesenteric glands, but without cheesy degeneration, and disseminated tubercles in liver and spleen. The other, 15 months old at death, had tubercular meningitis, with numerous granulations upon the convexity of the brain, and the other usual lesions of meningeal inflammation, with bronchial and mesenteric glands slightly enlarged and cheesy, and one of the former softened. In one case, then, in 18, the lungs had escaped the disease. Rilliet and Barthez state that they found the lungs non-tubercular in 47 cases in 312, and Hillier in 25 cases, in 160. In their cases, therefore, the lungs were exempt from tubercles in about 1 case in 7. But it is to be recollected that the statistics of these observers were prepared at the time when all cheesy degenerations were thought to be tubercular, and the bronchial and mesenteric glands are sometimes cheesy when there are no tubercles or lesions referable to tuberculosis in any other part of the system. I have records of two such cases, which I reject from my

statistics of tuberculosis, as there is no evidence that the disease was anything else than simple inflammation. Did I include these cases, my statistics would correspond with theirs.

Pulmonary tubercles in children under the age of three years are, as a rule, discrete, and disseminated through the lungs. In cases at this age, which have advanced to a fatal termination, we commonly find yellow tubercles from the size of a pin's head to a shot in the different lobes, many still semi-transparent if the disease has been of short duration, but if protracted most of them yellow, and here and there one softened and surrounded by condensed fibrous tissue. Around the semi-transparent or gray tubercles, many of which were growing, and therefore were in the state of active cell proliferation at the time of death, narrow vascular zones can often be detected by the naked eye.

Under the age of three years, tuberculosis exhibits but little tendency, perhaps none, to affect the upper lobes sooner or in greater degree than the lower.

The following are the statistics relating to the site of the tubercles in the lungs in the cases which I have examined. All, it is to be remembered, were under the age of three years:—

Tubercles disseminated throughout the lungs	26 cases.
Tubercles disseminated throughout the two upper lobes	3 cases.
Tubercles disseminated through right middle lobe and left lower lobe only	1 case.
Tubercles disseminated through left upper lobe only	2 cases.
Tubercles disseminated (few and semi-transparent) in left lung only	1 case.
Tubercles disseminated in three points in right, and two in left lung	1 case.
No tubercles in lungs	2 cases.
	36 cases.

Between the ages of three and fifteen years, statistics show that the upper lobes are more liable to tubercles than the lower; but the difference in liability is not great. In many cases occurring in this period, the different lobes are affected nearly simultaneously, and not very infrequently the upper lobe is the last which is involved. In October, 1866, I made the post-mortem examination of a boy who died in the Children's Service of Charity Hospital, at the age of fifteen years, and small scattered tubercles were found in the lower lobe of the left lung, while all other portions of these organs were healthy. Rilliet and Barthez, who include in the same statistics all cases from birth to the age of fifteen years, found gray semi-transparent tubercles

In the right superior lobe in	63 cases.
In the right middle lobe in	43 cases.
In the right lower lobe in	55 cases.
In the left superior lobe in	65 cases.
In the left inferior lobe in	54 cases.

The same observers found yellow tubercles in the

Right superior lobe in	40 cases.
Right middle lobe in	28 cases.
Right inferior lobe in	39 cases.
Left superior lobe in	35 cases.
Left inferior lobe in	31 cases.

It has already been stated that tubercle originates in a circumscribed inflammation. On the other hand, tubercle, especially when softening commences, is itself an irritant, exciting inflammation around it. Inflammation occurring from this cause is obviously likely to be protracted, continuing for weeks or months, unless the tubercular matter is eliminated by ulceration. The highly vascular and delicate lungs of the young child are very liable to inflammation when they are the seat of tubercles, and as the tubercles are disseminated, the pneumonia is commonly more extensive than when it occurs from ordinary causes. In fifteen, or nearly one-half of the cases, there was pneumonia affecting portions of one or more lobes, or an entire lobe. From the extent and position of the solidified portions, it was obvious that in most cases the inflammation originated from the irritating effect of the tubercular matter, while in others it was due to hypostatic congestion, occurring in consequence of the long-continued recumbent position and the feebleness of circulation. In these fifteen cases the seat and extent of the inflammation were as follows:—

Nearly entire right lung	2 cases.
Nearly entire middle and lower lobe	1 case.
Entire left upper lobe	2 cases.
A considerable part of both lungs	1 case.
Posterior parts of both lower lobes	4 cases.
Posterior part of left lung	1 case.
Left lower lobe, and right middle and lower lobes	1 case.
Left upper lobe (contained a large cavity) and posterior part of left lobe	1 case.
Nodules of inflamed lung around tubercles	2 cases.

The inflammation in about one-third of the affected lobes was due to hypostasis, as it occurred in depending portions, extended but little into the lungs, and sustained no relation to the amount of tubercle.

In seven of the cases there were pulmonary cavities as large in proportion as we ordinarily find in tuberculosis of the adult. The seat of one was in the right lower lobe; of two, the left upper lobe; of one, the right upper lobe; of another the right lung, its exact seat not stated; and in the remaining case the cavity, which was the largest of all, occupied the interior of all three lobes on the right side. Some idea of the size of these cavities may be learned by the following extracts from the records. 1st Case.—"A small superficial cavity communicating on one side with a bronchial tube, and on the other side with a small circumscribed collection of pus in the pleural cavity." 2d Case.—"Cavity of the size of a hickory-nut." 3d Case.—"Cavity of the size of a large hickory-nut." 4th Case.—"Cavity three-fourths of an inch in diameter." 5th Case.—"A large abscess." 6th Case.—"The cavity occupied nearly the whole of the interior of the left upper lobe." 7th Case.—"About half the right lung excavated into a cavity which extended through the three lobes."

Circumscribed pleuritis, produced by tubercles underneath the pleura, was observed in seven cases. It was ordinarily attended by little exudation, except the fibrin, but in one case a sufficient amount of serum had been exuded to compress considerably the lung. Pus was not observed in any notable quantity.

Emphysema was present in several cases, chiefly in the upper lobes, sometimes vesicular, with fulness or bulging of the lung, an anæmic appearance of it, and doughy, inelastic feel. In other cases emphysema was interstitial, producing little bladders of air under the pleura, especially towards the root of the lung, or separating the lobules by wedge-shaped or irregular interspaces filled with air. In one case air had escaped from an emphysematous bladder into the right pleural cavity, causing pneumo-thorax and collapse of the lung.

Next to the lungs the bronchial glands are more frequently diseased than any other organs, in the tuberculosis of infancy and childhood. They undergo the successive structural changes which characterize glandular inflammations, namely, hyperplasia, and more or

fewer of them cheesy degeneration and softening. In the state of hyperplasia the firmness is diminished, and they have a pale flesh color. Cheesy degeneration commences in one or more points in the gland, sometimes in the peripheral, sometimes in the central portion, and it extends till the whole gland presents the well-known cheesy appearance. When the gland softens the thick liquid presents a puriform appearance, consisting of amorphous matter, fatty particles, and the shrivelled and disintegrated cells of the gland. Soon pus cells occur, and their number increases.

Microscopy shows no anatomical difference between the hyperplasia or cheesy degeneration of the lymphatic glands occurring from inflammation, and that from tubercle; but since the bronchial and mesenteric glands are not often cheesy or greatly hyperplastic from simple inflammation, and are commonly not only greatly enlarged, but cheesy in the tuberculosis of young children, we conclude that the inflammation which gives rise to this hyperplasia and degeneration in such cases is of a tubercular character.

Rilliet and Barthez state that the bronchial glands were tubercular in 249 cases in children, while the lungs were tubercular in 265 cases. All cheesy glands, it is to be recollected, they considered tubercular. In 4 of the 36 cases which I have examined, no record was preserved of the state of the bronchial glands; in one case there was no perceptible hyperplasia and no cheesy degeneration; in two there was hyperplasia, but no cheesy degeneration, while in the remaining 29 cases there was cheesy degeneration of more or fewer of the enlarged glands, or parts of them, with occasional softening. In the fact that the bronchial glands are tubercular and enlarged, we have an explanation in part of the fact, that the symptoms in the tuberculosis of young children differ from those in the adult, since Louis found the bronchial glands tubercular in only twenty-eight per cent. of the adult cases of tuberculosis which he examined, and Lombard in only nine per cent. A gland pressing upon the recurrent laryngeal or pneumogastric nerve, or the trachea, may give rise to dyspnœa and a cough; or on the descending vena cava or one of the venæ innominatæ, to congestion of the brain and meninges, inter-cranial serous effusion, and even thrombosis in the cranial sinuses. The fact that a softened bronchial gland not infrequently is eliminated from the system, by ulceration, into a bronchial tube or the trachea, is well known. In one case which I observed the ulceration had destroyed portions of three of the cartilaginous rings of a bronchus, and the aperture was plugged by a cheesy fragment of a softened gland which protruded. Occasionally, it is stated by authors, the ulceration is into one of the large vessels of the mediastinum, or even into the œsophagus.

In no case did I find tubercles in the heart or pericardium, though they have been observed in rare instances in the latter. The mesenteric glands were enlarged by hyperplasia, and more or less cheesy, in 30 cases; in their normal state, to appearance, in two cases, and in the remaining 4 cases their condition was not stated. In most of the cases the mesenteric glands were smaller and less cheesy than the bronchial, but in a few instances the mesenteric were larger than the bronchial and more cheesy.

It is a noteworthy fact, as bearing on the causative relation of these glands to tubercles, that not infrequently the amount of hyperplasia and cheesy degeneration of the former was very considerable, while the tubercles in the lungs or elsewhere were small, even minute, semi-transparent, and evidently of recent formation.

The following table exhibits the state of the principal abdominal viscera in the 36 cases:—

	Liver.	Spleen.	Kidneys.
Tubercular	12	22	1
Non-Tubercular	16	6	21
Not stated	8	8	14
Fatty	5	0	0

In no instance did I observe tubercular softening in the abdominal organs, and a large proportion of the tubercles in the liver, spleen, and kidneys, were still in the first stage. In the 5 cases in which the liver was recorded fatty, this state of the organ was obvious to the sight, as it is in tuberculosis of the adult. A moderate excess of fat in the hepatic cells may have been present in some of the other cases, but it was not sufficient to be appreciable without the microscope. It is to be remarked that in the five cases in which the liver is recorded fatty, this organ contained no tubercles. The spleen is seen to have been the most frequent seat of tubercles of all the viscera, except the lungs. In fourteen cases the intestines were examined; and in five, tubercles discovered developed in the connective tissue. The intestinal tubercles were small, and ulceration had occurred of the mucous membrane which covered them.

The brain was examined in fifteen cases. In twelve cases the amount of cerebro-spinal fluid varied from ℥ ss. to v., by estimation. In two others the records state that there was a considerable amount of this fluid, the exact quantity not being given, while in the remaining case congestion of the brain and meninges was noticed, but nothing was recorded in regard to the amount of cerebro-spinal liquid. The increase of the cerebro-spinal fluid in tuberculosis is attributable to wasting of the brain, a *hydrocephalus ex vacuo*, and in some cases to passive congestion and serous transudation, due to feeble circulation, or obstructed flow from the pressure of bronchial glands on the vessels within the thorax, as already stated.

Tubercles were present in the pia mater in three cases: in two with fibrinous exudations; in the other without fibrine or other evidence of inflammation.

Original Communications.

REGIMEN A MORE EFFECTIVE PROPHYLACTIC AGAINST MIASMATIC AND EPIDEMIC INFLUENCES THAN THERAPEUTIC AGENTS.

By JAMES S. BAILEY, M.D.,

ALBANY, NEW YORK.

The intelligent physician is well aware that the sulphate of quinine, taken in small doses at stated intervals, will, in the majority of cases, prevent an attack of miasmatic fever, and, if contracted, will modify its severity.

It has been very successfully used upon some plantations in the Southern States, and has in many instances so fortified the system as to prevent an attack of yellow fever in persons constantly breathing an atmosphere charged with the epidemic influence.

For how long a period it will act thus is not well determined. Some claim for it an indefinite period. My observations convince me that if it is long persisted in it ceases to act as a prophylactic. Tonics may be used until they produce debilitating effects upon the system, and why may we not anticipate a loss of power and consequent failure in this respect when the system has become accustomed to it?

The writer now recalls an instance of an intelligent physician practising in a highly malarious district, who used to employ the sulphate of quinine in his own person, as a prophylactic against the absorption of miasm. His system became accustomed to its use and it lost its remedial power. When he once succumbed to an attack he was not so decidedly impressed with its action as were those not habituated to its use.

After a long residence and experience among diseases of this character, I became convinced that a well-regulated diet served more effectually to protect the system than any known therapeutic agent.

The writer, during sixteen years of active practice in his profession in a malarious atmosphere in Alabama and Texas, never contracted a chill, while much of the time exposed to the scorching rays of a noon-day sun and the humid night atmosphere. The same was true in reference to the exemption of every member of his family;—a fact so noticeable that many were anxious to know the cause.

The secret was simply this: our meals were regularly served and our food healthfully cooked. We breakfasted immediately upon rising in the morning, and ate supper before sundown. Between the setting and rising of the sun persons are more exposed to the influences of miasm than at other times. If at any time any member of the family did not have an appetite for such food as was prepared, some other dish that he could relish was substituted, thereby effectually preventing too long a period of fasting, for persons are much more liable to contract malarious fevers upon an empty stomach than when digestion is healthfully progressing.

Another fact should be observed. In such climates, even in midsummer, before sunrise and after sunset there is much humidity of atmosphere, and it was my custom nearly the whole year, every morning and evening, to have a small fire kindled, to rid the air of this noxious element.

The bilious miasmatic diseases usually commence early in June, and last until late in autumn. It was not uncommon during certain seasons, in some families, to find nearly every member confined from sickness of this character, with scarcely well ones enough to wait upon the sick. If these precautionary and dietetic means are sufficient to protect the system, every person should not only know the fact, but practise it.

The truthfulness of these statements will be further sustained by the fact that after the close of the war, when servants were free, and consequently were unwilling to perform labor at any price, in any family, for more than a few days at a time, our meals were irregularly served and imperfectly cooked.

The health of the family soon bore perceptible evidence of the change, as one after another fell an easy prey to the atmospheric influence.

These facts not only hold good in miasmatic diseases, but are equally true in epidemics of yellow fever. The writer, without having been acclimated, passed through several severe epidemics of this disease by strictly adhering to these principles, and escaped without contracting the disease.

Coffee serves as an excellent antidote against malaria. The French creoles, living upon the sullen and stagnant bayous of Louisiana, are in the habit of taking a cup of strong hot coffee before rising in the morning. Planters who cause their servants to take a cup of strong hot coffee before going out in the morning dew have experienced a remarkable exemption from malaria.

Residents in a malarious atmosphere should never leave the house without having breakfasted first. Individuals who have made this an invariable rule, have experienced a remarkable immunity from these diseases, and still live in the enjoyment of health, while others disregarding these precautions have passed away.

This explains why there are so many widows in such climates. The men are exposed to out-door life, and suffer from such causes, while the women are protected within doors and escape.

The foregoing principles are of practical and vital importance, especially in new countries, on river bottoms, where vegetation is rank and of rapid growth, and in all regions where miasmatic diseases abound.

For this reason practical facts have been presented that cannot be disputed.

The susceptibility to the influences of disease is in proportion to bodily debility. The system has less power to repel diseases and destructive agencies early in the morning, in consequence of long fasting during the night. The man who crosses the Pontine marshes near Rome before breakfasting, is sure to die from some malignant fever, while he who first takes a hearty meal passes through without harm.

When food enters the stomach it stimulates and excites more active circulation of the blood; the stimulating influence of nutriment derived from food prevents the mischievous and pernicious ingredients from entering the circulation. The laws antagonizing the effects of miasm are ascertained with certainty, and "one ounce of a preventive is better than one pound of cure."

The human system is strongly inclined to fall into irregularities, and repetitions soon produce habits, which, if not corrected, may last a life-time. Countless multitudes have consequently been inveigled into the various forms of dissipation, such as drunkenness, venereal excesses, using tobacco, &c.

If a nap is indulged in to-day, to-morrow about the same time sleepiness is experienced; the same is true with irregularities in eating; the appetite soon becomes fitful, the digestion deranged, the system loses its power of resisting the various diseases, and the victim falls an easy prey to dangerous and incurable maladies.

Excesses of any description, particularly drinking, and venereal, should not be indulged in during any exposure to epidemics. If so, the system is much more liable to succumb, and inevitably death must follow.

The pernicious effects of the early morning air in a miasmatic region upon the debilitated body and the unresisting stomach are known, and their laws of action are recognized, but human skill has failed to discover the physical properties of that ingredient. The analysis of this subtle poison and disease-producing atmosphere by the best known chemical tests has revealed nothing unusual.

We have learned that these deleterious agencies are resisted by the healthful stimulus of food introduced into the stomach, and if the digestion remains vigorous, and food is taken in sufficient quantities, and at regular intervals, they are comparatively harmless.

New Uterine Dressing Forceps.—Dr. G. Pepper, of Philadelphia (*Am. Journ. Obstetrics*), recently exhibited to the members of the Philadelphia Obstetrical Society a pair of long uterine dressing forceps, which allowed of the removal of the blades, and the adaptation of a pair of curved ones instead for carrying various therapeutic agents into the cavity of the uterus. The sound also separated, and the entire number of pieces readily slipped into the bivalve speculum, thus enabling them to be carried in the vest pocket.

Progress of Medical Science.

Treatment of Phthisical Sweating.—M. J. Guyot has found the phosphate of lime, in two to six gramme doses a day, to be a capital remedy for the sweating of phthisis and rheumatism. He never found the least inconvenience.

Treatment of Hysteria.—M. Guillemin, in *Lyon Medical*, recommends the inhalation of ethereal tincture of valerian for the space of one or two minutes as most successful in cutting short an hysterical seizure. Under its influence the hysterical attacks have always yielded and a pleasing lassitude ensued.

The Continuous Current in Hemiplegia.—Dr. Althaus mentions the case of a man, aged fifty-two, who, whilst writing, suddenly lost the use of the right arm. There was complete paralysis of forearm and hand, and nearly complete anæsthesia of hand and fingers. A current of twenty cells of Daniell's battery was applied to the left hemisphere for one minute on several occasions, and the same was applied to the radial and ulnar nerves, with the effect of restoring the power of the affected arm completely.

Simple Method of Examining the Throat.—In the *Revue Médicale* for March 19th is a suggestion by Dr. Guillaumot (of Poligmy), which, from its simplicity, deserves notice. Instead of having recourse to lowering the tongue with spoon or paper-knife, he makes the patient *yawn slowly* and deeply, while facing a natural or artificial light. After one or two minutes' instruction, the tongue is seen to subside and sink into the cavity of the floor of the mouth, the uvula is carried up in raising the tonsils and the pillar of the velum palati, and the examination of all these parts is thus facilitated. The method has the advantage of being a natural one, and is peculiarly applicable in the case of children.

Recurrence of Calculus.—Mr. W. Coulson says the rapidity with which calculus often recurs after operation is remarkable, and he recommends, as a prophylactic, washing out the bladder daily with lukewarm water.

Radical Cure of Corns.—We are glad to find a radical cure for these torments of civilized life, suggested by M. de Pontevés. It consists of the destruction both of the cuticular cuirass and the underlying cutis. The surface is covered with a vesicating plaster well charged with cantharides powder. After leaving this on twenty-four hours the cuticle will be found raised all around the "cuirass" of the corn; this is now taken off and a coating of tannin laid on the exposed and tender surface, then a tannin ointment laid over the part, the rationale being, firstly, the destruction of the cuticular covering, and then the application of the tannin to the gelatinous cutis—in fact, "tanning the corn."—*Medical Press & Circular.*

Electricity as a Therapeutic Agent.—Dr. R. Reynolds says a muscle may be paralyzed by something wrong in the tissue of the muscle itself; by something which cuts through the nerve which should connect it with the cord; by something destroying that part of the cord from which the nerve arises; by something destroying or cutting across the cord higher up than the origin of the nerve; or by something which damages the brain. Now in brain disease there is no diminution in the contractility of the paralyzed muscle when the galvanic current is applied, and in spinal disease in some cases this is the case. Feigned disease can often be made out by means of the galvanic battery.

Self-Illuminating Ophthalmoscope.—Dr. Lionel Beale, F.R.S., has devised an instrument for ophthalmoscopic examinations which promises to be a boon to future observers. A simple brass telescope tube, about one inch in diameter, has a lamp fixed to one side of it, and with another tube, in which is placed a reflector and ophthalmoscopic lens. This arrangement entirely obviates the necessity for the dark room for ophthalmoscopic observations. The patient is told to look with the other eye at an object some twelve feet distant, in order to enlarge the pupil.

Dr. D. C. Black on Gonorrhœa.—Dr. Black, of Glasgow, does not think that any irritant, whether chemical, physical, or vital, is quite sufficient to give rise to a gonorrhœa, and that "the majority of females who communicate gonorrhœa do not suffer from it themselves," as has been said by some authorities. He lays down two propositions—1. That married men have never been known to contract gonorrhœa from their wives; and, 2. That in remote country districts, and in islands, where there is no prostitution, gonorrhœa is never seen, save as an importation. The incubation period is from four or five days to some weeks. Gonorrhœa, then, is a local specific inflammation. His own firm conviction is that, when once the specific irritation sets in, neither diluents nor cooling drinks are of any use. Contrary to Mr. Hutchinson's views, Dr. Black thinks that in injections the amount of irritation and the strength of the injection should be in an inverse ratio. He is persuaded that sulphate of magnesia should not be administered in the acute stage. He likes as injection a mixture of sulphate and acetate of lead, three grains of the former to two of the latter, with a drachm of glycerine in an ounce of water; half of this injected four times a day. Repeated injections he prefers to retaining the solution. At the same time he administers cubebs. Chloride of zinc, three grains to the ounce, or a drachm of tannin with half a drachm of borax, and one ounce of glycerine in seven ounces of water, are recommended as injections.

In connection with the same subject he says that erection of the organ in chordee may to some extent be prevented by the internal use of bromide of potassium, opium, and camphor, and the local as well as internal use of belladonna and cold baths. In epididymitis he recommends leeching and hot fomentations in the acute stage.—*Medical Press & Circular.*

Skimmed Milk in Disease.—Dr. Donkin advocates the use of skimmed milk in albuminuria, diabetes, and fatty degeneration. The milk should not be boiled, but taken warm or cold, and six or seven pints may be used by an adult in the twenty-four hours. The cream must be very carefully removed, Dr. Donkin says, as it is injurious in cases of diabetes. The milk should therefore stand twenty-four hours, when the weather will permit it, before being skimmed.

Paralysis of the Bladder.—Dr. Van Holsbeck has employed, with success, electricity in paralysis of the bladder. He introduces an instrument into the cavity and another into the rectum, connects them with the poles of an ordinary machine, and allows the continuous current to pass for a quarter of an hour. In seven sittings he has cured paralysis which had resisted all other remedies.—*Med. Press and Circular.*

Permanganates for Fetid Expectoration.—An in-

teresting case occurred in the wards of the Hospital at Grenoble under Dr. Charvet. A man of forty-three years of age, consumptive, suffered terribly from the offensive nature of his expectoration, which compelled him to be placed in a separate room. Carbolic acid was prescribed, but produced only the slightest effect. Dr. Charvet then tried solution of permanganate of potash in water. The success was very striking, the stench at once being diminished, and in the course of ten days quite removed.—*Med. Press and Circular.*

Regeneration of Nerve-Tissue.—Voit has recently proved the reproduction of the cerebral tissue in the pigeon, and the coincidence of this reproduction with almost complete renewal of the cephalic functions. MM. Masius and Van Laer, Professors in the University of Liège, deduce from recent experiments—detailed at length in the current number of the *Monthly Microscopic Journal*—that the spinal cord in the frog can recover rapidly a loss of substance which has taken place in its own tissues, and repair its primitive anatomical and physiological properties.—*British Medical Journal.*

The Lymphatic Spaces of the Eye.—The last number of the *Quarterly Journal of Microscopical Science* contains a good *resumé* of Schwalbe's paper on the lymphatic spaces of the eye, contributed to the first part of Schultze's *Archives of Microscopical Anatomy* for the present year. In this paper are described the lymphatic spaces of the posterior division of the eyeball, which include the perivascular spaces of the retina, the perichoroid space with its efferent channels, and finally, a lymphatic space between the outer and inner sheaths of the optic nerve, which, without communicating with the other two, opens directly into the arachnoid sac of the brain. Between the inner surface of the sclerotica and the outer layer of the choroid is a space which was recognized by Arnold as a serous cavity, and to which the name "arachnoidea oculi" might be given. It is distinct from the lamina fusca, though in part occupied by connective tissue, elastic fibres, and stellate pigment cells. The opposed surfaces are smooth and shining, and, after treatment with nitrate of silver, exhibit epithelial markings with oval nuclei. It is most distinct in white rabbits, but cannot be demonstrated in the eye of man, on account of the difficulty of obtaining fresh human eyes. When filled with a colored fluid by injection, the space was found to reach backward to the neighborhood of the entrance of the optic nerve, and forward as far as just under the ciliary processes. The injection left the ball at four points corresponding to the entrance of the venæ vorticosæ, and cross sections showed that the veins were encircled by the injection. On escaping from the globe, the injection filled the capsule of Tenon, which again was found to communicate backwards, by a cylindrical channel surrounding the outer fascia of the optic nerve, with the arachnoid space of the skull. Besides the canal just spoken of as surrounding the whole optic nerve, to which the author gives the name of "supravaginal" space, there is another included between the two fasciæ of this nerve, which he calls the "subvaginal." This is continuous with the arachnoid, but does not communicate with the proper lymphatic spaces of the eye.—*Lancet.*

The Statistics of Cases of Anæsthesia by Chloroform and Ether.—Dr. E. Andrews, of Chicago, Ill. (*Chicago Medical Examiner*), has collected 209,893 cases of anæsthesia, so as to determine the relative dangers of the administration of chloroform and ether. The figures obtained give us 92,815 cases of anæsthesia by ether, and 117,078 by chloroform. Among those cases of anæsthesia by chloroform, 43 deaths occurred, showing the ratio of mortality to be 1 to 2,723. Among those by sulphuric ether, 4 deaths occurred, showing 1 death to 23,204 cases. It is evident, therefore, that the ratio of mortality, in surgical anæsthesia, by chloroform, is about eight and a half times greater than by ether.

Prof. A. has compiled a table of anæsthesias by mixtures of chloroform and ether, which shows 2 deaths in 11,176 cases; ratio of mortality, 1 to 5,588. From this it would seem that the mixtures have proved twice as safe as chloroform, and about four times more dangerous than ether. With regard to the new anæsthetic, bichloride of methylene, he states in concluding, we have as yet no decisive results, but the English journals report a single death among about 7000 cases.

The After-Treatment in Cases of Peripheral Linear Extraction.—R. H. Derby, M.D. (*N. Y. Med. Journal*), gives the subjoined after-treatment of Prof. A. Von Graefe, in cases of peripheral linear extraction, which he regards as highly important:—1st. That a fine and soft material be used as compress, and not a coarse charpie with hard threads. 2d. That the charpie be carefully arranged, so that when the hand be laid closely upon the compress, only a flat surface and nothing of the convexity of the eye be felt, and so that a moderate pressure upon the compress shall cause the patient no pain whatever. 3d. That the three turns of the bandage over the eye shall not alone keep the compress in its place, but afford a fully equable support for the surface of the eye from the lower to the upper fold of transmission. His rule is to change the bandage on the evening of the day of operation, and again the morning after. There is absolutely no objection to lightly opening the lids, and, by candle-light, cautiously looking at the lower part of the cornea. The patient should never be allowed to have the least sensation of pain in the region of the wound, that is to say, that does not absolutely depend upon the process of healing. The evening after the operation the patient should feel quiet and disposed to sleep. On no account should he pass a sleepless or uneasy night. If a subcutaneous injection of morphia has not already been made, on account of the pain from the wound, then, in order to encourage sleep, a dose of three grammes of chloral hydrate, in mucilage and sugar, may with advantage be given.

Effects of Bromide of Potassium in the Treatment of Young Children.—E. Montard-Martin, Phys. to the Beaujon Hospital (*N. Y. Med. Jour.*), recently read a paper on the above subject, which is translated by J. Cummiskey, M.D. His conclusions are as follows:—1st. Bromide of potassium, administered in moderate doses, is tolerated perfectly well by children of tender age. 2d. By its sedative action it relieves the insomnia of young children, whether this insomnia be calm or accompanied with agitation and cries. 3d. Administered to infants suffering from affections during the period of dentition—characterized by agitation, insomnia, cough, etc.—it succeeds frequently in relieving these complications, and by its judicious use may sometimes prevent convulsions. 4th. Bromide of potassium should not be given to children suffering from diarrhœa. 5th. In certain exceptional cases in which nervous erethism is predominant, bromide of potassium will have a most prompt and decisive action.

An Excellent Wash for Stomatitis Follicul0sa.—A writer in the *Am. Journ. Dental Science* recommends the following wash: ℞. Bromi puri, gr. vj.; Kali hydrobromi, gr. xxiv.; Aquæ destillatæ, ℥ ss. M. S. To be applied on ulcerations.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

OUR THERAPEUTICS.

THE medical profession of to-day are so wedded to the doctrine of expectancy that it requires no little moral courage to protest against it. From the extreme of polypharmacy, it has drifted into the other of doing little or nothing in the way of intelligent medication. It is true that our knowledge of the laws of disease has so much increased that our present ideas are in the main diametrically opposed to those held a quarter of a century since. This is indeed gratifying, and is the reward of much patient study, much laborious investigation, and much clinical research. As the result also of these studies we have been led to alter so very materially our notions as to the formerly accepted theories of the action of drugs that we have reduced our materia medica accordingly. So far, too, this procedure is perfectly natural, and is in strict accordance with the relations of cause and effect. We have not, however, stopped here, but have gone to the length of discarding the majority for the sake of a few, and have at the same time refused to admit others in their places. While we have been devoting ourselves to the study of other departments, we have allowed that of materia medica to dribble into a disgraceful nothingness, practically regarding it as a cumberer of true scientific progress, when in reality it should, in the very light of our advanced knowledge of physiology and pathology, be one of our most reliable aids.

The chief object of the physician is the cure of disease, or, if this be impossible, the mitigation of suffering. All his investigations must tend to that end, and if he stops short of it he betrays the confidence of the community in a wanton and highly culpable degree. Of what benefit is it to the patient to learn from his medical adviser the precise nature of his malady, the condition of his kidney under the microscope, the size and shape of his heart and the position of his valvular lesions, the mechanism of the cardiac murmurs, the nature of the process by which his lung is decaying piecemeal, the true explanation of an anasarca, the appearance of the cells from his tumor, or the rarity of his disease? This is certainly very satisfactory to the pathologist, but the poor patient looks at the matter practically. He at least is not expected to understand all the many reasons why, nor does he specially care to do it; his one and only legitimate aim is relief from suffering. One of the main duties of the therapeutist is this mitigation of suffering. It is not enough for him to assure the sufferer that his discomforts and agonies will soon cease without interference. He must be as ready to treat symptoms as to attack the disease itself. There is altogether too little of this done, and our patients are beginning to notice it. The physician who is the accomplished prescriber is the one who always retains his patients, because he is on the alert to keep him free from pain or any uneasiness. We dare not ask how often this reasonable desire of the sufferer is practically frustrated by the medical attendant if he be a deep-dyed expectant; and how much the real value of our art suffers, and will continue to suffer, in the estimation of the community, in consequence of the persistence of his practices.

The self-limited character of many of the more common diseases may for the present be established; but have future experiments with hitherto untried remedies nothing of promise in them? Must we fold our arms contentedly and look no farther? Have we arrived at the limit of our usefulness to poor humanity, and must we in future narrow our studies to physical diagnosis and pathology?

While the arguments in favor of the "let alone" treatment in self-limited diseases are comparatively few, those which might be applied to the arrestable and preventable maladies are still fewer. If we are to make advancement in the curative art we must strive to lessen the list of self-limited diseases, at the same time cutting the controllable ones much shorter. Diagnosis and pathology have opened up the way for us, but as therapeutists we are far in the rear. Investigations of diseased parts, in the hospital ward and in the dead-house, have taught us a great deal as to the nature of disease and the morbid changes which occur under different circumstances. We are being shown what we have to cure, and it is now the business of the therapeutist to learn how to cure it. This can only be done in a rational way by a proper and thorough study of the action of medicine. Herein the profession of the day are lamentably deficient, and, despite the light which science has thrown on other departments of our art, we do not much excel our ancestors. Our results of treatment are by no means brilliant in comparison to theirs, and too many of us are ignorantly groping in the uncertain light of empiricism. If the science of therapeutics received in general as much attention as it should, it is reasonable to assume that there would not be so many sceptics as to the action of drugs, and life would consequently be proportionably lengthened. Let each practitioner put the question seriously to himself, how much he individually is doing to fill up the gap of ignorance in this particular, and how few can present

a clear record. There are only a very small number of progressive men who are willing to follow the lead of the faithful pioneers who are making for us new paths; while a very large number are entirely oblivious as to what is going on about them. The time has come, if the majority of the profession are determined on progress, to look beyond whiskey, iron, and quinine, and study anew the properties of some of the older preparations, at the same time being always ready to give the newer ones a conscientious and unprejudiced trial. The means are abundant; all that is wanting is the skill and determination to adapt them to the end. There is no practitioner of the present day who can truthfully affirm that he is so well satisfied with his remedies that he needs no addition to his list. When we can find one who is, we can assure him that he will make his reputation at once by giving to the medical world his complete materia medica. Until this occurs, however, we contend that it is the bounden duty of every one to lend a helping hand to the science of therapeutics, especially at a time when there is so much distrust of the power of medicines and such blind confidence in the vis medicatrix naturæ.

Reviews and Notices of Books.

THE PREVENTIVE OBSTACLE; OR, CONJUGAL ONANISM. The Dangers and Inconveniences to the Individual, to the Family, and to Society, of Frauds in the Accomplishment of the Generative Functions. By L. F. E. Bergeret, Physician-in-Chief of the Arbois Hospital (Jura). Translated from the Third French Edition, by P. De Marmon, M.D. New York: Turner and Mignard. 1870. 12mo. pp. 182.

THE work before us is designed to call the attention of the practitioner to the physical penalties of imperfect coition. It is pretty well understood by physicians that the habit of preventing conception is very prevalent, and that many diseases of the generative functions are the result; but our author seems to have run wild on the subject, looking at the practice as the one great and almost only cause of all the ordinary neuropathies that are so common in every community. If such be really the case, there is another way aside from mere general assertion to prove it. We can understand how fraudulent connections may induce metritis, sterility, and hyperæsthesia uteri, but when we are told that cancer is not unfrequently the result, we imagine our author is attempting to prove too much.

The style of the work as a whole seems more fitted to minister to a morbid curiosity than to establish any strictly scientific point, and opens it to the suspicion that it is intended more for the general than the professional reader.

ANATOMY, DESCRIPTIVE AND SURGICAL. By Henry Gray, F.R.S, Fellow of the Royal College of Surgeons, and Lecturer on Anatomy at St. George's Hospital Medical School. The Drawings by H. V. Carter, M.D, late Demonstrator of Anatomy at St. George's Hospital, with additional Drawings in the Second and later Editions by Dr. Westmacott. The Dissections jointly by the author and Dr. Carter, with an Introduction on General Anatomy and Development, by T. Holmes, M.A. Cantab., Surgeon to St. George's Hospital, &c., &c. A new American from the Fifth and enlarged English Edition, with four hundred and sixty-two Engravings on Wood. Philadelphia: Henry C. Lea. 1860.

GRAY'S Anatomy has been so long and so favorably known to the student of medicine that we feel it unnecessary to do more than refer to the evident improvements in the new edition. In the first place, we observe that the portion devoted to General Anatomy has been entirely rewritten, and is now presented in the form of an introductory chapter of 113 pages, illustrated by a large number of new engravings, furnishing the student with a clear and admirable introduction to the study of microscopic anatomy. This chapter includes a subject entirely omitted in former editions, viz., the processes of the development of the fœtal state.

The body of the work also has undergone careful revision and rearrangement, and several errors have been corrected. A number of new illustrations will be found, besides some important additions to the text. The new edition has been reprinted under the supervision of Dr. Richard J. Dunglison, whose acquaintance with the wants of American students has enabled him to make some changes in the arrangement of the volume, which render it more convenient for purposes of reference. Altogether it is unquestionably the most complete and serviceable text-book in anatomy that has ever been presented to the student, and forms a striking contrast to the dry and perplexing volumes on the same subject through which their predecessors struggled in days gone by.

TALKS TO MY PATIENTS. By MRS. R. B. GLEASON, M.D. New York: Wood & Holbrook, 15 Laight st. 1870.

THIS is a superficial work, running over the whole category of female diseases, and keeping constantly in view the number of cases "we" have cured, after other treatment had proved unavailing. The book is neither more nor less than a plausible advertisement, intended to attract patients to some water-cure establishment in which the author is personally interested.

THE AMERICAN JOURNAL OF SYPHILOGRAPHY AND DERMATOLOGY. Edited by M. H. HENRY, M.D. Published quarterly. New York: F. W. Christern, 77 University Place. 1870.

THE title of this journal sufficiently indicates its character, if we remember that the term syphilography comprehends, as announced by the editor, "all diseases, whether general or local, having a venereal origin or lesion." The object of the journal is to lay before the profession everything of interest or value in connection with the large and important class of diseases that come within its scope. The plan of the journal includes original articles by the highest authorities, communications, reports, records, translations from foreign journals, criticisms of the latest publications, therapeutical notes, and a paragraphic summary of the current literature on the subject, both in this country and abroad. So far as we may judge by the two numbers already issued, the plan laid down for the conduct of the journal will be fully and admirably carried out. The original articles include communications from W. Boeck, W. H. Van Buren, R. W. Taylor, R. F. Weir, E. L. Keyes, Foster Swift, and M. H. Henry. The selections and translations are fresh and interesting; and, if the journal maintains its present standard of excellence, it will soon become indispensable, not only to the specialist, but to the general practitioner.

RENAL DISEASES. A Clinical Guide to their Diagnosis and Treatment. By W. R. BASHAM, M.D., of London. Philadelphia: Henry C. Lea. 1870.

THIS is a small but complete and valuable treatise, and really seems to contain nearly all that is definitely known at the present time concerning the symptoms, pathology, and treatment of renal diseases. The work is divided into three parts. The first part treats of the causes, pathology, and treatment of acute nephritis in all its varieties; the second part treats in like manner of chronic nephritis; while the third part is devoted to the properties of the urine, chemical, physical, and morphological, and their clinical significance. In

this connection the author informs us that all urine, whether from healthy persons or diseased, is capable of forming oxalate-of-lime crystals. There is therefore, in his opinion, no such thing as an oxalic diathesis. The author is evidently an acute observer and an independent reasoner, and thoroughly master of his subject. His book should be read by every practitioner and student in the land. A number of illustrations have been added to the American reprint.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MAY 25, 1870.

DR. A. L. LOOMIS, VICE-PRESIDENT, in the Chair.

WAS THE INTUSSUSCEPTION THE PRIMARY OR PROXIMATE CAUSE OF DEATH?

DR. J. K. MERRITT, of Flushing, N. Y., after exhibiting a specimen on behalf of a candidate, gave the following history of a case in that connection:—

H. R., aged 3 years, was a robust and well-proportioned boy, excepting head, which was unusually large, but well balanced; had always enjoyed good health from birth, excepting slight ailments common to infancy. One morning this boy ate heartily of corned-beef hash for breakfast; after this he appeared perfectly well and playful. At noon he partook of a simple lunch, such as bread and milk. Soon after this meal, while playing, he began to complain of brief abdominal pain, which recurred at short intervals, with complete intermissions. During the latter part of the afternoon nausea occurred, with the paroxysms of pain, and finally vomitings ensued with apparent relief. The matter ejected from stomach was undigested food. I saw him soon after and found him simply languid, with no symptom of ailment excepting a slower pulse than natural, and nausea when rising up from a supine position or drinking a small quantity of water, both of which he was inclined to do. I saw him again the same evening; he then had a slight fever, and complained of some abdominal pain; was also suffering from an irritable stomach; thirst, but no appetite; all other conditions apparently normal. He had had two natural dejections from the bowels during the afternoon and evening. During the night he was feverish, restless, thirsty, and inclined to vomit the small amount of water allowed to drink. Next morning I was hastily summoned, and on my arrival found him in a convulsion, which had already existed about 15 minutes. He was put into a hot mustard bath, with cold affusion to head. No relief ensued, and in about 20 minutes, while in this convulsion, he died.

Autopsy 30 hours after death. A careful examination of the organs of chest and abdomen disclosed every one as perfectly healthy, excepting an intussusception in the middle third of the ileum, about three and one-quarter inches in extent, which was tightly jammed, and apparently occluding the calibre of the bowel. There was evidently an injection of the vessels of the bowel in this locality, but no lymph or other signs of inflammation. No examination of cranium was made.

Query: Was the intussusception the primary or proximate cause of death?

DR. FINNELL remarked that it was very frequent to find intussusception in children who had died suddenly in convulsions, and he was inclined to think that in the great majority of instances the lesion occurred during the agony, and was more a result than a cause.

DR. LOOMIS thought that the convulsions were due to undigested food, and that in a child of that organization they were not to be controlled when they once commenced; and further, that the intussusception was purely sympathetic and temporary, there being no well-marked signs of inflammation of the gut or neighboring parts.

DR. ROGERS was of the same opinion, and thought that the explanation was well put, inasmuch as a loss of appetite—which, by the way, this child evidently did not have—was one of the most common and prominent symptoms of organic intussusception.

EXTENSIVE OSSIFICATION OF FALX CEREBRI.

DR. FINNELL presented a portion of the dura mater, with the attached falx cerebri removed, from a man aged fifty, who had died from apoplexy, the result of softening of the brain. The specimen presented the most extensive so-called calcification that he had ever seen, it being nearly five inches in length, nearly an inch in breadth, and a full quarter of an inch in thickness.

DR. ROGERS believed that the invariable rule in such cases was that the deposit was not due to calcareous matter, but to true bone, an opinion concurred in by Dr. Mason.

DR. FINNELL expressed the same belief, remarking that such deposits of osseous matter were seen to occur in proximity to bony tissue, and *vice versâ*.

DR. FINNELL also exhibited the uterus of a woman upon whom an abortion had been produced by a quack, and who died as the result of puerperal metritis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

ADJOURNED STATED MEETING, APRIL 18, 1870.

DR. GEORGE T. ELLIOT, PRESIDENT, in the Chair.

INTRA-UTERINE MEDICATION.

DR. J. C. NOTT read a paper upon this subject, from notes of which we give a full abstract.

After a brief *résumé* of the leading points of an article which he had published in the *Journal of Obstetrics* (Nov., 1869), upon the various indications for intra-uterine treatment, the various means devised to meet them, and especially a new and safe instrument for uterine injection, the speaker said that his attention had been of late particularly drawn to the chemical effect, upon the bloody and other uterine discharges, of most of the agents commonly introduced into the uterus in the topical treatment of its diseases. The albumen, fibrine, and corpuscles of the blood, constituting, according to Flint, Jr., about four-fifths of its bulk (according to those who reject their water of constitution, about one-fifth), are coagulated, by some of the agents roused, into a solid mass. Most of these, indeed, have a greater or less coagulating effect, not only upon blood, but as well upon mucus and the various leucorrhœal discharges, which are highly albuminous. The important points are, that some kind of chemical reaction takes place between these agents and the fluids found in the uterus and vagina, and that this must greatly modify the effect of their application. A portion or the whole of the substance introduced will be neutralized and rendered inert by the discharges which it meets. Even chromic acid, for example, may be injected into a uterus filled with blood, and pour out of it without irritating the vagina, which is extremely sensitive to its action. Stillé mentions cases where

pieces of lunar caustic have been swallowed without serious injury. Corrosive sublimate has such an affinity for albumen that the white of an egg is its best antidote. Tyler Smith says that leucorrhœal discharges, coagulated by injections, may remain in the vagina for days, and then come away in an egg-shaped mass. If this can take place in the vagina, with its large opening, it is far more likely to occur in the body of the uterus with its narrow outlet. That such coagulated masses were sometimes retained in the uterine cavity for an indefinite time, producing great irritation and protracted discharges, the speaker had had abundant occasion to observe.

If, then, inert chemical compounds are formed between the materials introduced, by injection or otherwise, into the uterus and the fluids found there, the extent to which the uterine mucous membrane is affected by the application will depend upon the proportion between the two. And this will explain the discrepancies among gynæcologists regarding the value of various intra-uterine remedies. In this city the favorite method of application is by means of the probe, wrapped with cotton and dipped into a solution of the medicament. Dr. Sims uses a curved glass rod, without the cotton, and to this not more than two or three drops can adhere. The result of this treatment must be in most cases either negative or harmful. The greater part of the substance upon the probe will be rubbed off in passing the cervical canal. What remains will very likely be thrown into a puddle of albuminous fluid; or if the uterus be flexed, as is so often the case, it will probably come in contact with only one side of the organ, where the mucous membrane may be perfectly sound, and so be only damaged by the application; or it may meet with a tuft of exposed vessels, and produce the most violent uterine colic, metritis, ovaritis, etc. It is essential to the proper effect of remedies that, preparatory to their introduction, the uterus be cleared out as far as possible by suction with a syringe. But often the surface is coated with a tenacious discharge, to remove which we must employ a weak solution of muriatic acid, common salt, or some other solvent of albuminous matter.

Led thus to the belief that intra-uterine medication had hitherto been most unsatisfactory, the speaker had made a series of experiments, which he hoped others might follow up, so as to place this practice upon a more firmly established basis.

Styptics arrest hemorrhage either by coagulating the blood or by constricting the vessels. To secure their action it is necessary to keep them for some little time against the bleeding part; this an injection into the flooding uterus often fails to do, though it may form a coagulum that will act as a tampon and so stop the flow. The most effective way to control uterine hemorrhage is to inject iodine, and then plug the cervix with cotton and persulphate of iron.

To determine the coagulating effect upon albumen of different reagents, the doctor had added to white of egg, in test-tubes, a few drops each of undiluted solution of persulphate of iron, saturated solution of chromic acid, same of tannin, same of nitrate of silver, pure carbolic acid, and Churchill's tincture of iodine. These experiments were repeated before the Society and the test-tubes handed round. The iodine produced only a flocculent precipitate; but each of the other reagents combined at once with about its own bulk of albumen, in a firm globular coagulum, which could neither be diffused throughout the mass nor increased in size by shaking.

Next, to imitate the most watery of the uterine leucorrhœal discharges, the white of egg was diluted with four parts of water, and submitted to the reagents as before.

Persulphate of iron (Squibb's solution) coagulated the whole mass into a jelly.

Saturated solution of chromic acid instantly formed a coagulum, less solid than before, but still too consistent to pass through a canula. Chromic acid the doctor considered a much more powerful intra-uterine remedy than persulphate of iron, and far more dangerous. If not neutralized by the secretions it might produce the most terrible results. It was the most destructive to animal tissues of all agents used in medicine, and a strong solution would, in twenty minutes, completely dissolve a small animal. Even its most cautious introduction into the uterus by the probe was not free from risk.

Tannin produced a coagulum easily washed away, giving the mass only a syrupy consistence. This agent had, in common with persulphate of iron, the merit of being but slightly irritant.

Nitrate of silver produced a profuse, flocculent precipitate, and sulphate of copper had the same effect. It was generally agreed that nitrate of silver is one of the harshest applications to the uterus, particularly in the fluid form. The speaker had once injected a five-grain solution, and came so near killing his patient that he had never experimented with it since. It was remarkable that it did not produce such severe results when applied to the uterine cavity in the solid form. To prove this, and to show how inefficient must be its ordinary superficial application, a long extract was read from Courty, who leaves the solid stick to dissolve in the uterus, as he claims with much benefit and no danger.

Alum produced no coagulum and so might probably be advantageously introduced into the uterus.

Saturated solution of carbolic acid in water produced a pulverulent precipitate. The doctor had found the injection of this solution give much pain, where that of iodine caused almost none. It was of much value, however, as an antiseptic.

The precipitate produced by iodine was not such as to interfere with the fluidity of the dilute albumen. There was no really potent remedy of which the uterus was so tolerant as of this. Even Churchill's tincture, undiluted, would be well borne where the most cautious use of nitrate of silver would give trouble. Of all intra-uterine remedies, iodine had most commanded the confidence of the profession. It was something more than a stimulant, a caustic, a styptic; it was a remedy *sui generis*, whose curative action could not be fully explained. The fact of its ready absorption made it especially valuable, where we wished to affect the deeper tissues of the uterus, as in chronic inflammation. Nitrate of silver or chromic acid, on the other hand, had only a stimulant or caustic action—indeed the absorption of the former would produce toxic effects.

In intra-uterine treatment we should begin by testing the tolerance of the organ, first with tepid-water only, and then with a very weak solution of iodine. Though commonly almost destitute of sensibility, yet under some conditions the uterus becomes, like inflamed periosteum or peritonæum, exquisitely sensitive. But even in these cases it can usually be educated to bear injections of the requisite strength.

The result of a series of experiments upon blood, was, in general, that most of the reagents above mentioned produced a coagulum firmer than that with pure white of egg. As before stated, the coagulum formed in the uterus by persulphate of iron, though temporarily arresting hemorrhage as a tampon, might afterwards keep up the flow by its irritant action. In a case

of metrorrhagia close at hand the speaker had used this styptic, by the advice of Dr. Sims. It had at once stopped the hemorrhage, but for five days since a discharge had been taking place. Yet there were some cases where we must use the iron and hazard the risks.

With regard to the treatment of endometritis and its complications, gynæcologists might be divided into three schools—the cutting school, the cauterizing school, and those who use no intra-uterine treatment, but depend upon vaginal injections, hygiene, and constitutional remedies. Perhaps a fourth school should be added—the eclectic, combining some elements of each of the others. Drs. Sims and Emmett were generally regarded as the representatives, *par excellence*, of the cutting school. The speaker had been much associated with them; and though he had often heard them charged with needless use of the knife and scissors, yet he had rarely seen bad results from their operations. They were both extremely cautious in the intra-uterine use of caustics; and he did not hesitate to say, from actual observation, that caustics often do more harm than comes from cutting the cervix. The Doctor said that he had but half finished his paper, but the remaining part would be published. He then exhibited his double canula for uterine injections. The injecting-tube was very small, and ran within the return-tube, which was four or five times its size and had a very large eye, so placed as to be kept clear by the injected stream. Even with all this advantage, it was often impossible for the return-current to take place after the injection of some of the solutions above described, their coagulation of the uterine fluids was so complete and instantaneous. This was demonstrated upon a rubber uterus filled with albumen.

Dr. Fordyce Barker was anxious that a paper so original in its investigations and suggestions should receive a worthy discussion, and hoped that a meeting would be assigned for this after the completed article was in print. The subject was one of the greatest importance, and it was especially fittting that a full discussion of it should be brought out in this city, where intra-uterine medication might almost be said to have originated, and where it had been pushed to a more audacious extent than anywhere else. Previous to such discussion, he would ask Dr. Nott to investigate the action of another agent, which had been his own special favorite for the last fifteen years,—sulphate of zinc. He was wont to use it especially in those more or less trying cases of menorrhagia, so frequently associated with the climacteric period, and unconnected with prominent organic disease of the uterus, malignant or fibroid, although the organ was commonly enlarged. In some of these cases the flow would be profuse, in others long-continued. For the treatment of excessive flooding in such cases, he was accustomed to employ a paste made by rubbing up one ounce of sulphate of zinc with two drachms of glycerine. This was of just the right consistence to be easily introduced into the uterus through a canula the size of Simpson's sound. He thus introduced into the cavity from three to five grains of the paste; and, in most cases, one or two applications would be followed by entire cessation of the hemorrhage. There was commonly no recurrence, and he had never seen any unpleasant symptoms result.

Dr. Peaslee could not agree to the analysis which gave eighty per cent. of the blood as organic matter, though this point was of little practical importance with reference to the subject in hand, since the very small percentage of fibrin was sufficient to coagulate the whole mass of blood for a time. As to the natural secretions of the uterus, cervix, and vagina, they were all mucous, and contained not a trace of albumen; but the abnormal discharge from an inflamed mucous membrane was albuminous, and so the experiments presented bore directly upon the conditions met with in practice. The egg obtained an albuminous envelope in passing through the oviduct, because the mucous membrane of the oviduct was in an unnatural condition of congestion. The speaker continued:—

I am very glad to have a paper upon this subject from a man of the well-known independence and accuracy which characterize the writer of this one, and I cannot help thinking that such cautious remarks, from such a Nestor of the profession, must have their good effect upon some of its younger members, who I fear are being led on too rapidly and recklessly by the brilliancy of intra-uterine medication. Just at this time the subject is become one of the most prominent, as it is one of the most important, before the profession; and, as Dr. Barker has remarked, New York is the field where its problems are to be worked out.

Dr. Kammerer had already shown that if we would use intra-uterine medication with any certainty of success, we must first wash out the uterus by copious injections. Dr. Nott has to-night shown us the reason. Still the practice of introducing substances into the cavity of the uterus is to a great extent merely empirical. There are numerous points yet to be settled with regard to it. Many persons even now doubt whether such treatment should ever be resorted to; and though I think their doubts will be dispelled in the future, yet I will say that intra-uterine medication should be resorted to in comparatively very few of the cases of uterine disease, and never except in those actually requiring it. What are those cases? What substances should be used? In what manner should they be used? Not one of these questions is yet settled. I have my own opinions; and should be willing to give the results of my experience, if the discussion is to take up the general subject of intra-uterine medication. But that might hardly be in order.

I have one or two points to suggest with reference to the nomenclature of uterine diseases. We need new terms with definite meanings. I would enlarge the anatomical nomenclature of the uterus to correspond precisely with that we now use of the heart. I would speak of the *endometrium*, the *metrium*, and the *perimetrium*. Thence we have *endometritis*, *metritis*, and *perimetritis*. In utra-uterine medication we are seeking to make our applications to the endometrium, which can only be done, as Dr. Nott has said, by first getting it perfectly clean.

As an addendum to the Doctor's remarks upon persulphate of iron (which is, I think, perfectly harmless,—certainly so in metrorrhœa and metrorrhagia), I would say that in some cases it is only necessary to apply a plug to the cervix to get the tampon effect which he describes. In cases of metrorrhagia attending the menopause, where I could not delay to send home for a syringe, I have taken a wad of cotton, tied a string to it, soaked it in a solution of persulphate of iron, letting it absorb all it would, and then passed it into the cervix. In the flaccid condition of the cervix at this period of life you can easily introduce such a plug the size of a hickory nut. It almost immediately causes contraction of the neck around it, and this contraction may continue for some hours, perhaps four. The tampon is perfect for that time, and the hemorrhage, of course, is arrested; for the uterine walls are not distensible as in post-partum hemorrhage, and you have put a stopper into the full bottle.

The injection of a solution of alum, a drachm to the ounce of water, I have once tried in a case similar to those first mentioned. It arrested the hemorrhage

instantly, and gave no after trouble. I have also made use of Cagliari's solution, of which alum is the chief ingredient, with similar result.

With regard to chromic acid, I had occasion to remark to the Obstetrical Society, three or four years since, that the only way in which I could explain the fact that cotton could be dipped into a saturated solution and passed into the uterus without harm, was that the acid never touched the endometrium at all. For if you pass a probe through the cervix, it is just as impossible for it to carry the acid to the endometrium as for a big weasel to go through a small rat-hole without touching a hair. Still you do sometimes get ill effects from chromic acid. I have used it upon a few cases, and though without ultimate bad results, yet with such symptoms as at first to give me much alarm. I do not know of any case where I should invoke its full effect, for I know of none where I should wish to remove the endometrium. I might be willing to touch a granulation with it, if I could be sure of touching that only; but of this one can never be sure. I find iodine perfectly safe and effective. So is the strong solution of persulphate of iron; so, too, are the saturated solutions of alum and of tannic acid. I do not see, then, why I should make use of such an agent as chromic acid or nitrate of silver, except, perhaps, now and then in very weak solution. And I agree with the Doctor that we should in every case begin with a weak solution, until we see what the uterus will bear. I have seen chronic endometritis (or, as I should call it, chronic *congestion* of the endometrium) cured by weak solutions often repeated. In cases of retroflexion, I think the first thing in the treatment should be to replace the uterus. I should never think of first applying anything within it, and should know of no surer way of producing adhesions of the organ in its false position than to apply chromic acid, which not rarely produces metritis. If there were adhesions already, and the uterus could not be replaced, then I would not use chromic acid; for other remedies would serve as well.

Dr. Emmet.—I must confess myself very much astonished in listening to the remarks of Dr. Peaslee. I have probably employed chromic acid more than any one else, for the last fourteen or fifteen years, using it every day in the Woman's Hospital, and getting good effects from it. And now I feel very much as Rip Van Winkle did when he woke up,—to be told that I have never been able to pass it into the uterus. Used with its own weight of water, I do not find it any stronger than nitrate of silver. I have never seen over half a dozen cases of bad effects following its use, and those were rather due to accident than to the remedy. I should prefer the nitrate of silver, were it not that the long-continued use of it hardens the tissues. Chromic acid, with an equal amount of water, is, I believe, no stronger; I have never seen it attack healthy tissue, or irritate the vagina any more than solution of iodine.

One remark further. I decidedly object to being considered a member of the "cutting school." I do not belong to any school. I suppose it would be impossible for two men to come to more opposite conclusions from the same data than Dr. Sims and myself. I claim to be eminently conservative; and some time since* I read before this society a paper on *The Surgery of the Cervix*, in which I endeavored to present these views. But if you give a dog a bad name it will stick to him. I then said that the largest number of times I had divided the cervix in any one year was twenty-three. Since reading that paper I have operated five times. I never resort to surgical means except as a last resort, as it were; and I think many of those who do not make a specialty of uterine diseases operate a great deal more than I do.

Dr. Peaslee had no doubt that Dr. Emmet was so accustomed to the use of chromic acid that he was sure of getting it into the cavity.

Dr. Kammerer.—I presume, Mr. President, that Dr. Nott reckons me in his second class of practitioners—those who deal chiefly with uterine injections. If so, he is quite right, with the exception that of late I have a slight leaning towards the cutting side. For many years I have made this subject my special study, and I use uterine injections every day. By these I mean not only those into the cavity of the uterus, but also applications to the cervical canal. In fact, the cases which require local treatment of the uterine cavity are exceedingly rare, as compared with the numerous cases we observe daily where the cervical canal demands treatment. I am in the habit, nevertheless, of injecting tepid water into the cavity of the body, as a means of cleansing it, before making any application whatever, and this even where I only intend to treat the canal of the cervix perhaps up to the internal orifice. After dilating the canal, I invariably make the injection of tepid water. I have been led to do this from knowledge and experience of the fact that albuminates do form whenever the secretions come in contact with certain salts and acids employed in the local treatment.

It is chiefly in cases of flexion, especially anteflexion, that the cavity of the uterus is often found dilated and filled with mucus. The contained fluid is rarely, however, of a purulent character; indeed, it rarely consists of thick mucus, but it is mostly clear, transparent, serum-like. This is in contradiction to what has been said by many others, but I nevertheless insist upon it. I am in the habit, as I said, of dilating the canal; and I frequently observe that, after cleansing the cervical cavity up to the internal orifice by a very small sponge, or bits of cotton, then, on dilating the internal orifice, a teaspoonful or more of clear, serum-like fluid flows out, evidently from the cavity of the body. In these cases of catarrh of the uterine cavity, I have always insisted, and do now insist, that it is extremely important to keep the canal wide. We should learn from affections of the bladder how to treat an organ like the uterus. We observe that when there is stricture of the urethra, the bladder becomes hypertrophied, and soon after the urine becomes stagnant. There is a similar condition of the uterus whenever there is stricture of the internal orifice; and you find in the cavity the thin mucus I have described. These cases often improve by simple dilatation of the internal orifice, repeated once or twice a week for a certain length of time. Gradually the hypersecretion diminishes, sometimes with no local treatment at all. But sometimes I have found that the contents of the cavity were not simply serous, but mucous and purulent; and in these cases I have invariably resorted to intra-uterine remedies.

My memory will not serve to bring up all the points that occurred to me during the reading of the paper; but a few facts I may state. That chromic acid and nitrate of silver coagulate not only the bloody, but also the catarrhal secretions, is a matter of common observation. Those who have treated hemorrhages from erosions of the cervix, which are sometimes very considerable, know that, if they bring persulphate of iron or chromic acid in contact with the blood flowing from the erosion,

* Feb. 8, 1869. The paper may be found in *Am. Jour. Obst.* for February, 1869, and report of the meeting in Med. Record, vol. iv., pp. 19, 63.

large coagula of albuminates will form, which obstruct the vagina and may be difficult to remove. Of course, if you introduce these agents into the cavity of the bleeding uterus, clots are formed which produce trouble before they are expelled. It is not necessarily the case, however, that a strong solution, injected into a cavity full of mucus, will simply form a neutral albuminate. If there be too little of the injection, the effect may be zero; but if there be more than enough to neutralize the secretions, then the caustic becomes active.

One part of Dr. Peaslee's remarks reminds me of a case that may serve to illustrate it. A lady who had been bleeding for three months came here for treatment and was sent to me. I examined her in the recumbent position. The uterus was somewhat enlarged, and the internal as well as the external orifice was moderately open. I introduced dilators, and, after full dilatation, injected cool water. To my great astonishment a fearful hemorrhage followed; while the patient was still there on the chair, the speculum filled with immense clots. I immediately resorted to a pretty concentrated solution of chromic acid, which was injected into the cavity without the slightest effect; the hemorrhage continued. I then made pressure upon the abdomen, and sponged out the vagina thoroughly, and thought I saw some erosions in the cervix. I took a brush and applied to them the concentrated chromic acid, and at once the hemorrhage ceased. Now if gentlemen think that by applying the plug to the cervical canal they have arrested hemorrhage from the cavity of the uterus, I believe that they have mistaken cases of this kind for those of hemorrhage from the cavity.

You know, Mr. President, that we have days when the devil tempts us to do just what we have often sworn we will never do. On such a day last winter, after reading what Courty and Tilt had recommended as the best treatment for uterine catarrh, I broke off a piece of nitrate of silver in the uterus, and resolved to make the trial. Now, when you break off, by accident, a piece of this caustic and leave it in the canal of the cervix, you generally find little trouble. The fragment may be easily removed with the forceps. But when you introduce the nitrate of silver into the uterine cavity, the result becomes very different, as this case and another will show. As I say, I introduced a piece of the nitrate into the cavity. The next day, the patient sent for me, and I found her in a very bad way. She had been having chills, and presented symptoms of intense prostration. It was four or five days before I could consider her fairly out of danger.

The second case was rather worse. In this also I had introduced a piece of the solid lunar caustic into the cavity of the uterus. It was upon that same ill-fated day last fall, when the Obstetrical Society was to meet at the house of Dr. Nott, that, on going to the meeting, I found a messenger from the patient awaiting me. She had been in excessive pain all day. Within twenty-four hours she took two drachms of chloral hydrate, without any effect whatever. She then had two subcutaneous injections, which gave some relief. For several weeks she lay in a very critical condition. Peri-uterine inflammation was developed, with a hard mass in one broad ligament, and it took about three months to get over this. During the three or four weeks that she lay in bed, she had parotitis of the right side; and she has now paralysis of the facial nerve, which I hope is only temporary. I could attribute the parotitis to nothing but my daring application. The patient is now slowly recovering.

Dr. Whitehead had, in cases of slight endometritis, as detected by the probe, made frequent applications of a concentrated tincture of iodine. He applied it on the cotton-wrapped probe and was sure it had reached the fundus. From this treatment he had gained not only amelioration, but positive cure. He related a case that had been under his care at the North-western Dispensary for about three years. When first seen, the cervix was immensely enlarged; the uterus was in a state of fixed retroflexion, as carefully determined; and there was purulent endometritis. To the cervix he had made applications of chromic acid, and of nitrate of silver melted on the probe, with no bad effect except that the too frequent application of the nitrate produced constriction and finally obliteration of the os, requiring incision and dilatation. Since then he had applied strong solutions of iodine, and the patient had improved remarkably. He had, in one case, found such fearful prostration, with vomiting, etc., from the introduction of a probe tipped with the fused nitrate into the cavity of the uterus, that he had ever since been very cautious about using anything but the strong iodine. He commonly employed the formula which was the favorite of Dr. Budd:—℞. Iodinii gr. lxxx., Potassii Iodidi ʒ ss., Spts. Rectificati f ʒ j. M.

Dr. Jacobi.—I am not expected to be an expert in these matters, and will occupy but a single minute. I wish to state that so far as carbolic acid is concerned, I have used the impure acid, so-called, undiluted in many cases, and have never seen any bad effects from it. As to the nitrate of silver, the advantage it offers is, that it will never act beyond the place where it is applied; and it is this advantage which has made it the pet of many practitioners. But I confess that, from this very fact, I have little faith in its producing any effect upon the whole lining membrane of the uterus, when introduced in the solid form. I think it can only affect the limited part with which it comes in contact. I would simply recall a case I had years ago, where I dropped a piece of nitrate of silver into the right bronchus of a child, through a tracheotomy-opening; and several days afterwards had the chance to make a post-mortem. I found my piece of caustic upon the side of the bronchus, solid, embedded in albuminates, having done no harm. The very neighborhood of this piece of nitrate of silver was entirely intact. There was no inflammation or even congestion around it. I imagine, therefore, that in the uterus it would be the same—that its action would be strictly confined to the parts it touched.

Dr. Barker renewed his suggestion that a future meeting be assigned for the further discussion of the subject; and the President said that arrangements would be made to hear the conclusion of Dr. Nott's paper and have it fully debated.

The Society then adjourned.

Treatment of Aphonia by External Manipulation of the Larynx.—Henry K. Oliver, M.D., physician to the Mass. General Hospital, Boston (*The Am. Jour. Med. Sciences*), after alluding to the methods of treatment commonly employed in *aphonia from paralysis of muscles of larynx*, reports six cases successfully treated by external manipulation. This method consists chiefly in the compression of the wings of the thyroid cartilage in their posterior and upper part by the thumb and forefinger. In employing this method in paralysis of the adductors, the patient is instructed to make an effort to produce a sound, like that of *a* or *ah*, or any sound of the voice whatever, while compression of the larynx is being made. The result generally is that, after a little time, a feeble voice-sound is produced, and this is followed shortly after by the full restoration of the voice.

Correspondence.

PHYSICIANS AND APOTHECARIES.

To the Editor of the Medical Record.

Sir:—Not long since you saw fit to make some remarks upon "The Relations of Apothecaries and Physicians to each Other," wherein you condemned both professions for serious shortcomings. Any one who would read that article must, I think, be struck with the idea that your condemnations are intended to lean towards the apothecaries. The physician, it would seem, is let up rather easy, where reference is made to his practical acknowledgment of an imaginary reciprocal Code of Ethics. The undersigned is striving to be an upright pharmacist, and has been inclined to devote himself as far as has been possible to his legitimate sphere; but his experience has verified your assertion as to the impossibility, under the present system, of making a decent livelihood from the prescription business. And this fact is due almost entirely to a want of co-operation on the part of the physicians. Not only do many of them, even in the city, supply their own pills, in the form of the now fashionable dragées, but, being much wedded to the percentage system, they are much in the practice of writing in cipher, so that none other, save those compounders to whom they direct their recipes, can fill them properly. The recent melancholy case in Harlem is one in point, where a life was wantonly sacrificed to the cupidity of the physician in attendance. It may not be known to you that this system is now being carried so far in another direction, but with the same intent of defrauding the apothecary, by the establishment of stock companies of physicians, who own drug stores in different parts of the town, and who make it a practice of directing their patients to said establishments, boldly assuring them that at no other place will they trust their prescriptions to be put up. Can any unprejudiced individual blame the counter-prescribing as a compensation for these outrages?

Apothecary.

New York, June 1, 1870.

Medical Items and News.

Death of an Old Journalist.—Dr. Charles Jean Baptiste Come, the founder of the *Abeille Medicale*, recently died at the age of 74 years.

A Veteran Practitioner.—Dr. Zaccheus Bass, of Middlebury, Vermont, has practised medicine for 57 years. He was Surgeon of Volunteers in the war of 1812, and was at the battle of Plattsburgh in 1814.

Anæsthetics.—The late Sir Jas. Y. Simpson, M.D., Bart., in a second letter on the "History of Modern Anæsthetics," to Dr. Jacob Bigelow, of Boston, Mass. (*Boston Med. and Surg. Journal*) dated April, 1870—the last production from his pen—alludes to the three kinds of *anæsthetics* used in practice, as follows:

Nitrous Oxide Gas, introduced by Dr. Evans, of Paris, but originally suggested by Sir Humphry Davy, in 1800, and practically and successfully employed by Dr. Horace Wells, in Hartford, in 1844.

Sulphuric Ether, first used by Dr. Morton, at Boston, in 1846.

Chloroform, first employed in Edinburgh, in 1847.

The Manufacture of Chloroform.—According to the late Sir Jas. Y. Simpson, there is a single manufactory of chloroform, located in Edinburgh, which makes as many as eight thousand doses a day, or between two million and three million of doses every year—evidence to what a great extent the practice is now carried of wrapping men, women, and children in a painless sleep during some of the most trying moments and hours of human existence.

Prof. Nathaniel Chapman's Final Examination of a Medical Student.—A writer in the *Old Guard* gives his experience with this humoristic professor, who was so long identified with the Medical Department of the University of Pennsylvania:

"I shall not readily forget Chapman's manner to me when he examined me for my doctor's degree. I was terribly scared, and very much confused, so much so that when he asked me the first question, I hesitated, stammered, and at length said: 'I—I—don't know.'

"'Don't know? Pooh! pooh! You're sitting too near the fire. You're too hot. Draw your chair back, and take time. You know well enough.'

"His manner reassured me, and I answered the question correctly.

"'H'm! Didn't know, indeed!' And he resumed his queries, which I answered. Presently he spoke of a patient that he had seen that day, detailed his symptoms minutely, and asked me to make out the diagnosis. By this time my embarrassment had returned. Things grew very much mixed in my mind, and I fell back on a plea of ignorance.

"'I don't believe a word of it,' he said. 'You are only confused. You're too hot. You're too near the fire yet. Go over there by the window, and cool yourself. There, that will do.'

"His manner was so amusing, and his apparent belief in my real knowledge so earnest, that it relieved me of my confusion, and I not only gave my opinion of the disease, but even entered into a discussion and defended my views in the matter. When I had done he looked at me with a twinkle in his eye—few who ever saw it would forget his peculiar glance at such a time—and said: 'You are perfectly right. I knew you were too hot before. If you were a son of mine I'd thresh you. Never plead ignorance until you are sure you don't know. In the practice of medicine it is highly important to keep cool, and thus be able to think quickly. If I had taken your answer at first, I'd have dismissed you, and thought all my instruction thrown away. Instead of knowing nothing, you knew all about it. Now send in another gentleman to be hackled a little.'"

The New York Physician's Mutual Aid Association.—The By-laws and Charter of this Association having been placed in our hands, and having become somewhat acquainted with its character and objects, we cheerfully recommend it to the attention of the members of the profession in the counties of New York, Westchester, Kings, Queens, and Richmond, which are its boundary.

"Any regular member of the Medical Profession (of the above counties), and in actual practice, or teacher or professor in a medical school under seventy years of age, may be admitted a member."

"The object of the Association shall be to afford relief to the widows and children of its deceased members, by such contributions as may be required by the By-laws. Initiation fees $2, and an assessment of $1 from those under fifty years, and $2 from those over fifty years, payable on the death of any member in advance, for the next deceased member, so that the

amount due his widow and children can be paid within forty-eight hours, if need be."

There is also a permanent fund being created, and as soon as it amounts to a certain sum, out of the interest thereof the Trustees are empowered to make appropriations to the widow and children, in cases of *special* necessity.

The Association already numbers nearly three hundred members, including many of the more prominent of the profession. It is the purpose of the Trustees to double the number before the next annual meeting, and they therefore call upon the members to procure as many applications as possible, and if the number can be swelled to a thousand, so much the better for all interested. And why not?

We have given this brief outline of the Association, with our hearty God-speed. At some future period we may enter more fully into the benevolent features of this Association.

American Medical Association.—Dr. W. B. Atkinson, the Permanent Secretary of the American Medical Association, proposes shortly to publish an official copy of the last meeting at Washington. Those who are specially interested in the doings of the body will thus have an opportunity for consulting the proceedings in extenso, without the delay attending its appearance in the regular volume of the *Transactions*.

Prof. C. L. Ford, of the Long Island College Hospital, Brooklyn, N. Y., left on board the *Marathon* for Europe on the 21st ult.

We learn that he expects to return in time for his next course of lectures.

The Virtues of Sarsaparilla.—Dr. T. C. Allbutt, in *The Practitioner*, advises the use of sarsaparilla in certain cases of syphilis, and gives it as his opinion that the drug has gone out of fashion without sufficient reason. He quotes several of his own cases in which he obtained results from sarsaparilla that he could not obtain by either mercury or iodide of potassium.

Whence Cometh Petroleum?—Vast forests of sea weeds grow at the bottom of the ocean. The heat from the interior of the earth under the bottom of the sea distils the sea weed and liberates the oxygen from the hydrogen of the surrounding water and forms petroleum.

The Action of Tea upon Nursing Women.—Dr. William Goodell, of Philadelphia (*Am. Jour. of Obstetrics*), recently stated to the Obstetrical Society of Philadelphia, that tea seemed to him to act as a positive stimulant to the secretion of milk.

Polarization by Reflection First Discovered.—John E. Hurlbut, M.D. (*Chicago Medical Times*), reminds us, in his paper on "The Microscope," that it is to Malus, who, in 1808, discovered polarization by reflection, that we are indebted for the series of splendid phenomena which have since that period been developed.

The Action of the Polariscope.—So delicate is the action of the polariscope that it will detect, as Dr. Herepath has demonstrated, one-millionth of a grain of quinine, an amount so unappreciable, that the nicest means of chemistry fails in its discovery.—*Chicago Med. Times.*

Average Income of the Berlin Practitioners.—Dr. Schlesinger writes that the average income from the practice of medicine of each practitioner in the city of Berlin, is about 600 thalers—$450—per year. This would not pay the rent of a decent office in our city.

A New Alloy.—A new alloy of hydrogen and mercury, or hydrogenium amalgam, has been discovered by Prof. Oscar Loew, of the College of the City of New York.

A New Use of Electricity.—M. Scoutetten proposes to apply this agent to the rapid ripening and improving of new wine.

A Humiliating Spectacle.—The Paris correspondent of the *British Med. Journal* writes that a few weeks ago a motley multitudinous procession was seen proceeding to the cemetery of Mont-Parnasse. The crowd was chiefly composed of male and female rag-gatherers: the occasion of the muster of this filthy Parisian fraternity was the funeral of Dr. Genson, a man who quite recently had an excellent genteel practice, and a good social position. The bottle clothed him in rags, and made him the doctor of the rag-gatherers. His abilities were good. He prescribed across the counter to his patients, who were very numerous, and had unbounded faith in his skill. After his coffin had been placed in the *fosse commune*, three patients of the deceased delivered funeral discourses. The first speaker was an ex-notary; the second, an ex-advocate; and the third, an ex-sous-préfet,—all three now practising the nocturnal profession of street rag-gatherers, and inhabiting the Ile des Singes!

Speedy Cure of Aneurism.—Mr. Erichsen delivered a clinical lecture upon a case of aneurism of the profunda femoris, cured by compression in twenty-four hours on March 21st. There was a large aneurismal tumor at the upper part of the thigh in a patient, in which, on admission, neither thrill nor pulsation was discoverable at first, but which afterwards began to pulsate and increase in size. The pulsation was moving rather than expansile. The diagnosis of the case was that it was aneurism of the profunda femoris.

As pressure on the common femoral artery arrested the signs, Carte's compressor was employed; but the patient was irritable, and bore the compression very badly. Forty grains of chloral were administered, and he slept deeply for twelve hours, during which the compressor was maintained *in situ*. For the next twelve hours digital compression was employed, and all the signs ceased. Thus in twenty-four hours a cure was effected. The thigh decreased in circumference an inch and a half.—*Med. Press. and Circular.*

Morbid Sympathies of the Urethra.—In a recent clinical lecture by Mr. Paget he remarked on the morbid sympathies of the male urethra, which were quite peculiar to that mucous membrane. Syncope sometimes follows the passing of a catheter, as also epileptiform convulsions. These effects, however, only arise when the patient is standing, never when he is lying down. Rigor after passing catheters was said to be commonest in persons who had suffered from ague or lived in hot climates, and might often be prevented by the administration of alcoholic fluids. Mr. Paget mentioned that he had known death follow from simply sounding for stone in six cases. Pyæmia occasionally follows catheterism or lithotrity, apparently from irritation of the urethra, without any injury being done to its structure. Urethral rheumatism, he added, is a complaint presenting many points of resemblance with pyæmia. Any inflammation of the urethra may be followed by swelling and effusion into the joints, whether such inflammation were contagious or not.—*Med. Press and Circular.*

CHLORAL CAPSULES.—In the *Bulletin Générale de Thérapeutique* for March 30th, there is a paper by M. S. Limousin, on a new mode of administering the hydrate of chloral—namely, in capsules and comfits. The disagreeable impression left on the mucous membrane of the mouth from the contact of the drug, and the fact that it, though solid and crystallized, is volatile and extremely deliquescent, forbid its administration in the form of a pill. M. Limousin was then led to avail himself of the property which chloral possesses of becoming fluid at a comparatively low temperature (114.8° Fahr.), to introduce it under a liquid form into capsules or comfits, in which it speedily solidifies. These capsules contain 20, 25, or 30 centigrammes of the drug, as the case may be.

THE GERM-THEORY OF DISEASE.—Dr. Bastian replies to Professor Tyndall's last letter in the *Times*, and denies the probability that lung-filtered air should be unable to produce putrefaction, and asserts that putrefaction may occur *in vacuo* and after the destruction of all germs. He declines at present to explain the particular facts alluded to by Professor Tyndall, considering it sufficient to point out that they do not necessarily bear the interpretation which had been given to them. —*British Med. Journal.*

A SINGULAR SPECIMEN.—Before the London Pathological Society, on April 5th, Dr. Beigel exhibited the pubic parts taken from the body of a member of the religious sect in Russia known under the name of the Skeptis. The penis, scrotum, and testicles are removed with one sweep. The specimen was the first which had been obtained in Russia, so successful had the sect been in preserving secrecy.—Dr. Beigel also exhibited some photographs of members of the sect showing the change in physiognomy following the removal of the genitals.—Mr. HULKE remarked that the same method is carried out in the Levant. Much difficulty was often felt there by the eunuchs in passing urine, and many carried a catheter.

A NEW TEST FOR ALBUMEN.—Dr. C. Meymott Tidy, Joint-Lecturer on Chemistry at the London Hospital, has noted that a mixture of equal volumes of acetic and carbolic acids is a far more delicate test for the presence of albumen than any other method that has been proposed. In using this test with urine, it is necessary to shake the test-tube, as some opacity is produced by the mere admixture of fluid, which, however, disappears on agitation.

LADY DOCTORS.—Two out of the five lady medical students in the Edinburgh University are in first class honors in Chemistry, and two in second class honors. In Physiology, one lady appears in first class honors, and three in second class honors.

TRANSMISSION OF SYPHILIS BY VACCINATION.—The late Austrian Minister of the Interior, Dr. Giskra, was asked some days ago by Dr. Roser, in the Parliament, whether it was known to him that a number of children in Styria had been infected with syphilis through vaccination. Dr. Giskra replied that it was true that fifty-five children had been infected through lymph obtained in Vienna by Dr. Kolisch.—*British Med. Jour.*

NEW SOURCE OF QUICKSILVER.—A layer of quicksilver ore has been recently discovered in the district of Sarawak, Borneo, which ore promises to be one of the richest in the world.

FOOD REQUIRED FOR MAN.—Man requires 1·23 of his weight in daily food, to supply the waste of tissue continually going on in his body; if the waste is greater than the repair, death ultimately ensues.

SQUILLS AS A POISON FOR RATS.—Recent experiments show that squills—*Scilla Maritima*—the bulb of which is much used in medicine, is not only a powerful poison for rats, but also one they are very fond of.

ANOTHER DEATH FROM BICHLORIDE OF METHYLENE.—While a healthy-looking man, æt. 40, was placed on the operating table of Guy's Hospital, London, for the purpose of having an iridectomy performed in each eye, one drachm (measured) of methylene was administered. The operations on both eyes were completed, and the patient left on the couch, while one of the assistants noted down the nature of the operation. About 3 minutes had elapsed, when it was noticed that the respiration was shallow and catching. There were a few gasping inspirations, then all ceased. For about ten minutes the galvanic current, and for about an hour artificial respiration, were employed without success. —*British Med. Journal.*

DISCOVERY OF CELLS AND FIBRES IN DENTINE.—Geo. B. Harriman, D.D.S., Boston (*The Am. Jour. Dental Science*), opens, in an article on "The Discovery of Cells with Fibres in Dentine," with the question—What are we to understand by the term tubuli? By Kolliker, and almost every other writer on the subject, "tubes and tubuli are hard pipes which admit of the passage of fluid." By the author of a paper in the *Dental Cosmos*, for February of the present year, they are likened to the "tubes of a boiler and hollow columns of a building." From repeated experiments, Dr. H. is prepared to demonstrate and prove that these so-styled "tubuli" are cells and fibres which radiate from the pulp cavity and terminate at the junction of the enamel and cementum. At this point these cells and fibres can be frequently seen as real soft solids, as much so as the fibres and cells in cartilage. A careful examination with a microscope of medium high power, from four to seven hundred diameters, will demonstrate, he thinks, that no fluid passes in these so-called "tubuli." What is seen are calcareous salts.

GENITO-SEMINAL NEUROPATHIA.—John P. Mettauer, M.D., LL.D., of Virginia (*Boston Med. and Surg. Journal*), believes that this malady, termed progressive locomotor ataxia, is quite a manageable malady, especially in its earlier stages. During the last 25 years he has treated numerous cases of this disease, and has yet to meet with the first patient not greatly benefited or cured. The writer adds that females are fully as often affected with the disease as males, especially those who have indulged too freely in sexual intercourse or masturbation.

MONUMENT TO DR. HORACE WELLS, THE DISCOVERER OF ANÆSTHESIA.—The Dental Association of Hartford, Connecticut, will shortly erect in that city a prominent monument or statue to the memory of Dr. Horace Wells, formerly a practising dentist, in honor of the great discovery which has conferred such blessings on suffering humanity.

ILLINOIS OPIUM.—William Proctor, Jr. (*Jour. of Pharmacy*), after carefully analyzing a block of opium two inches square, extracted from poppies raised in the State of Illinois, finds that the residue does not contain more than one-fifth of one per cent. of morphia. Assuming all of the white crystalline residue to have been morphia, it is sufficient evidence of the worthlessness of this so-called "opium," which is in reality merely extract of poppies.

On inquiry as to the manner of obtaining this substance, it was understood to be made by the process of Wilson, of Vermont opium notoriety, by expressing

the juice from the whole plant, leaves, stalks, and capsules, and evaporating the juice to the proper consistence without any extraction of the special juice of the capsules by incision.

Heroic Treatment.—Dr. Francis Mason, of London (*British Med. Journal*), in a late address before the Medical Society of London, gave an amusing account of the heroic treatment adopted in the days of Dr. Lettsom, not the least remarkable examples of which were the case of a lady to whom, for some irritation about the rectum, one hundred leeches were applied—she died exhausted by the hemorrhage; and also a case of ophthalmia, which required no less than two hundred leeches, besides free venesection, to arrest the inflammation.

The Average Duration of Sclerosis of the Nervous Centres.—Dr. Meredith Clymer, of N. Y. (*N. Y. Med. Journal*), states that the average duration of this affection may be put down at from eight to ten years. In 17 fatal cases, it lasted for two years in 2, five to ten years in 9, thirteen years in 2, seventeen years in 1, twenty years in 1, and twenty-four years in 1. The age of death in these cases was: from twenty-five to thirty, 2; from thirty to thirty-five, 5; from thirty-six to forty, 4; from forty-one to forty-five, 2; from forty-six to fifty, 2; from fifty-one to fifty-five, 1.

The Microscope.—The Microscopical Society of Illinois lately met in Chicago, and exhibited slides and instruments valued in the aggregate at $10,000. Among the most interesting specimens exhibited was a slide which contained the Lord's prayer, engraved on the 1-558th of a square inch, and distinctly legible through the microscope.

Secretion of Tears.—Before the Manchester Medical Society, at a recent meeting, Mr. Lund read a paper on the Effects of the Secretion of Tears on the Circulation in the Brain. He related the case of a lady who, about ten years since, after hearing suddenly of the death of a son, was seized with a violent paroxysm of grief, shed tears profusely, suffered for some days from frontal headache and great cerebral excitement, and then recovered. Lately, this same patient received news, by letter, of the supposed death of another son abroad. The circumstances were peculiar, and, when the letter was read, while all the family around were greatly affected, it was noticed that, contrary to her usual habit when much moved, she did not shed a tear. In about two hours afterwards, while sitting at dinner, she suddenly exclaimed, "Oh! my son, I shall never see him again!" and immediately she was seized with right hemiplegia. There was no other form of paralysis, and no aphasia. The total loss of power, with partial loss of sensation, in the right arm and leg remained for nearly five days, after which the paralysis gradually ceased, and, at the end of three weeks, all traces of it were lost. During this time, it was declared by her friends that she was never seen to shed tears. The inference drawn from these facts and from other singular cases referred to was that, on both occasions, under the excitement of intense grief, certain parts of the brain, most probably the thalami and striate bodies, which have been called the *emotional ganglia*, were the seat of vascular congestion; that, on the first occasion, this vascularity was in some way relieved by the secretion of tears, but, on the second attack, the secretion of tears not occurring, the congestion of the ganglia persisted for a certain time, and this state and the paralysis were associated together as cause and effect. It was assumed that one use of intense lachrymation, as an emotional secretion, was to relieve the excessive *intracerebral vascular congestion* of certain parts, which, if allowed to go too far or to be too long sustained, would damage the structures and cause suspension of their functions. The whole subject was illustrated in many ways, and the paper, which was very interesting, caused considerable discussion.—*British Medical Journal.*

Balsams and Cubebs in Diphtheria.—The treatment of diphtheria by balsams and cubebs has been for some considerable time before the profession, in consequence of the recommendation of Dr. Trideau and others. It is now attracting new interest in consequence of the recent publication of the results of the internal use of cubebs as prescribed in forty-two cases by Dr. Bergeron at the Hôpital Sainte-Eugénie. This method is recommended as a substitute for, and as superior to, the plan originally recommended by Bretonneau, subsequently practised and energetically enforced by Trousseau, of thoroughly cauterizing with the solid nitrate of silver the surfaces invaded by false membrane. The main object for which the caustic is used is to modify the morbid action of the mucous membrane, and thus, in particular, to prevent the formation of false membrane proceeding from pharynx to larynx; in other words, to prevent that form of diphtheria to which French writers, following Bretonneau, generally apply the term "croup," restricting the use of, and so giving an intelligible meaning to, the old and too loosely applied Scottish vocable. Here we do not mean that an affection has any pathological relation to "croup" when we say that it is croupy (*croupale*). Stridulous laryngitis is croupy, and laryngismus stridulus is croupy; but neither is croup, according to modern French nomenclature. Dr. Bergeron thinks that the object for which Bretonneau used caustic is more easily and certainly attained by giving cubebs internally. He says that children will readily take, in the course of twenty-four hours, from ten to twenty *grammes* of the *saccharure de cubèbe*. It is dissolved in water, and divided into several doses. —*Paris Cor. British Med. Journal.*

Local Treatment of Eczema Rubrum.—Dr. John Kent Spender says, in the *British Medical Journal*, the two main points in the treatment of this affection are, (*a*) to apply something which cures as well as soothes; (*b*) never to put over that application any impervious covering.

Eczema Rubrum is very common on the skin of the leg and of the ankle, and is often connected with varicose veins. The irritation which it causes may be alleviated by dusting the part with dry astringent powders, and by painting on the pharmacopœial preparations of glycerine; but it is seldom that a cure is effected in either case. Ointments of every kind are hurtful. After many trials of various remedies, I found, some years ago, that the common black wash (lotio hydrargyri of the *Ph. B.*) is a very effective application. I mix with it a tenth or twelfth part of glycerine by measure, and then shake it well. A small quantity of this mixture being poured into a wide shallow vessel (as a saucer), strips of linen rag are soaked in it; and, after being lightly squeezed, are placed evenly and smoothly round the affected part of the limb, a portion of the black oxide of mercury adhering to the linen. Each strip should overlap the one above by nearly a quarter of an inch, so as to present an uniform surface covered by the dressing. A *thin* calico bandage will secure everything in its place, and keep it so. Between the dressing and the bandage there should not, on any account, intervene any impervious covering, such as oiled silk or a sheet of gutta percha. Such may appear to have the immediate advantage of preserving the moist-

ure of the linen; but the disadvantage is decided and obvious—that the secretion of the diseased skin is prevented from evaporating, and it rapidly decomposes. Hence, not only is the eczema not cured, but fresh tracts of skin are liable to inoculation. A large area of the limb may become red, hot, and spongy, thin serum streaming out at every pore; and probably the limb is enlarged by œdema of the subcutaneous structures. Renew the dressings twice a day, and no harm follows their becoming dry, provided that they are completely saturated with warm water before removal. They are then easily taken off without hurting the patient or damaging the healing skin. Since 1860 I have treated a number of cases by the method now related, and I have been successful in all but three or four. And the defiant behavior of these few suggested the application of a strong nitrate of silver solution before putting on the linen steeped in black wash; and this plan answered completely.

Prostitution in Japan.—Prostitutes in Japan are obliged to live in certain quarters of the town, surrounded by high fences or canals. In Yokohama there are said to be 1,020 prostitutes in this forlorn quarter. But it seems that there is plenty of clandestine prostitution also, as the ill-paid officials are ready to be bribed by the poor slaves to man's ill-regulated appetites. The women attend at the lock hospital for examination weekly, and yet with all this, Mr. Acton mentions in his book that syphilis is particularly malignant in that city.

Flies the Propagators of Malignant Pustule.—The Paris correspondent of *The Chicago Medical Journal* asserts that M. Davaine has clearly proved that flies can inoculate the malignant pustule three days after having sucked the blood of an animal affected with this disease. He is not yet prepared to declare that three days is the extreme limit.

To Preserve Milk.—The Parisian method of preserving milk for a long period is as follows: Six grains of bicarb. pot. or sod. is added to each quart of fresh milk before the cream has risen, bottled, tightly corked, and then placed in a water-bath, heated to 190 degrees, and not more—the cork is then coated with wax.

Psoriasis.—Phosphorus is highly recommended for psoriasis. It should be administered both internally and externally.

Minnesota State Medical Society.—On perusing the *Transactions of the Minnesota State Medical Society*, we notice that this organization enumerates among its members quite a number of the recent graduates of the Medical Colleges of New York, who are distinguishing themselves in advancing medical science.

Where the First Dissection was Made.—The Venice correspondent of the *Chicago Medical Examiner* writes, that he stopped a few hours at Bologna in order to visit the *old* and once celebrated University of Bologna; an institution which numbered at one time 4,000 students and 300 professors, its medical school being for a long time the most celebrated in Europe. It was here that the first human body was dissected, and the first anatomical preparations made. The museum is still one of the most complete and extensive in the world, both in human and comparative anatomy. It is a curious fact that several of the most important chairs—those of History, Natural Philosophy, Literature, and even Anatomy, have at different times been filled by *ladies*. The University is still well maintained, there being some 400 students in attendance.

Mortality of Parisian Infants.—Fifty-three thousand infants are annually born in Paris; of these 25,000 are sent out to be nursed, and at the end of every year 12,000 or 13,000 of these little ones are dead.

Epileptoid Convulsions Caused by Carious Teeth.—Dr. John W. Booth, M.D., of Tally-Ho, N. C. (*Am. Jour. Med. Sciences*), recently visited an unmarried lady who had had daily epileptoid convulsions for four years, affecting principally some of the muscles of the neck and the right arm.

In giving the history of the case, she stated that her first spell came on during an attack of toothache. Upon examining her mouth, Dr. Booth found half a dozen carious teeth, which he immediately extracted. There has been no return of the convulsions since. The patient has improved considerably in flesh, and presents no anæmic phenomena, which previously existed.

Relations of Physical Forces to Disease.—Dr. F. Homer Blackman (*Chicago Med. Examiner*) states that his ideal method of studying diseases is by noting the temperature in connection with the physical forces. The following conclusions he believes to be warranted by recent scientific research; namely, that motion, chemical affinity, heat, light, electricity, magnetism, and nerve-force are convertible, each into the other, both qualitatively and quantitatively; that large quantities of these forces surround every form of matter; that these forces are particularly subject to change, in their relative proportions, especially when existing in relation to that form of matter known as gaseous; that these forces as they exist in the body are evolved during the processes of respiration, digestion, and assimilation; and that they sustain a certain quantitative and qualitative relation to each other, which relation cannot be disturbed without more or less disastrous effects being produced in the organism; that the relations sustained to each other are qualitatively the same in living as in organic bodies; that the stability of the relations differs much in different organisms, and also in the different stages of their development and growth; and, finally, that no system of etiology which does not recognize the influence of the so-called physical forces, singly and combined, in the production of disease, is worthy of serious attention.

Colors Used for Injection of the Liver.—The clever microscopist and pathologist, Dr. H. D. Schmidt, of New Orleans, La. (*N. O. Jour. of Med.*), recommends the following colors for injection of the liver: Prussian-blue for the duct, chrome-yellow for the artery, vermilion for the portal vein, and white for the hepatic veins. He formerly used chrome-yellow for the hepatic duct, but he finds the prussian-blue preferable.

New Publications.

Books Received.

The Medical Register of New York and Vicinity for the Year Ending June 1, 1870. Published under the Supervision of the N. Y. Historical Society. R. Lee Jones, M.D., Editor. Vol. VIII. New York: Bradstreet Press. 1870.

Erratum.—On reviewing the item in our department of Progress of Medical Science styled, "Doses for Hypodermic Use," published in the issue of June 1st, we notice that the quantity of water is put down in the solutions of Aconitine, Atropine, Strychnia, and Morphine as being ℥ j. It should read ♏ j.

Original Communications.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., PH.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

ARTICLE II.

MORPHOLOGICAL POSITION OF THE LIMBS—THEIR DEVELOPMENT AND SUPERFICIAL SYMMETRY—DETERMINATION OF CORRESPONDING BONES.

EVEN the brief of evidence already given may have had the force of virtual demonstration of antero-posterior symmetry; if not, further judicious questioning of the limbs will produce the desired result. It is possible to prove—if anything outside of mathematics can be proven—that the extremities are reversely repetitive. Type is set right-left; print is read left-right: one is a symmetrical impression of the other. So is each limb—in plan or 'idea,' that is, though actually distorted in answer to the requirements of teleology. A straight rod, plunged part way into water, looks bent; but the deceptive appearance is due to the medium, not to the thing observed: our vision is at fault; the difficulty is subjective, not objective; the stick is straight enough. Much of the difficulty we may meet with is rightly suspected to be due to imperfect and distorted vision of ours: teleology is a highly refractive medium through which to view morphology; it is nevertheless our only one.

At the outset we may successfully dispose of a glaring but superficial obstacle. By pronation, in cases of man and other animals that have a perfect radius and ulna; by a corresponding provision in other cases; both hands and feet point in the same direction—forward. Ends of fingers and toes are both anterior; anconal and rotular aspects of the terminal segments are in front of, respectively, carpus and tarsus. Here is asymmetry at once: for the fingers and toes should point in opposite directions; and furthermore, bones of the forearm are *crossed*, while tibia and fibula remain parallel. But a moment's reflection will suffice to convince us of the extreme improbability of such crossing of bones of a segment being their real morphological status; and how probable it is, therefore, that pronation, whether permanent, as in the horse, or temporary, as in man, is merely a teleological device. Supination not only removes this last obstacle, but dissipates the more serious one first adduced. Embryology * unmasks the forearm, and shows that such uncrossing of the bones of that segment is not only warrantable, but imperative.

The primitive limb-buds project at right angles from the sides of the body. Before the upper arm and thigh are fully evolved, there occurs a downward (*i.e.*, bellyward) flexion of each member, producing convexities corresponding to the future elbow and knee. The palms and soles are vertical and both face inward (*i.e.*, toward the median line of the body). With further growth, the elbow swings backward toward the side of the chest, the knee forward toward the side of the belly. The palms now look forward, the soles backward: the two limbs are up to this time essentially similar and symmetrical in position. Next ensues the gradual pronation of the forearm, producing asymmetry; that is thus seen to be an afterthought,* so to speak—not a morphological condition.

In comparing fore and hind limbs, therefore, in respect of their morphology, the first-named must be taken in position of perfect supination. Supposing now the body to be suspended horizontally, with the limbs hanging downward, and all the segments slightly flexed upon each other successively in opposite directions, the following would be the absolute and relative positions of the two members:—

Scapula (and scapular arch) pointing forward; ilium (and pelvic arch) pointing backward; humerus backward, femur forward; forearm forward, leg backward; carpo-metacarpus *backward*, tarso-metatarsus forward; the two latter segments bearing with them their respective phalanges, which consequently point in opposite directions, and would if flexed, bend under in opposite directions; but it is not necessary to take the digits into special account. The shoulder would point forward, the hip backward; convexity of elbow backward, of knee forward; convexity of wrist forward, of ankle backward; palms downward and forward, soles downward and backward; nails of all the digits uppermost, and looking toward each other. The back of the arm would correspond to the front of the thigh: the front of the forearm to the back of the leg; back of the hand to "instep," palms to soles, &c. Humeral condyles and articular surfaces look forward; those of the femur backward; the heads of these bones are both bent inward toward the axis of the body; their tuberosities or trochanters both look the other way. In short, the general antagonism and consequently the symmetry or antitypy of the two members is seen to be complete, except in one notable respect: the two-jointed thumb is on the outside, while the biarticulated great toe is on the inside, each of its own limb. By position they thus correspond each to a digit with three internodes; viz., thumb to little toe, and little finger to great toe: to this I shall presently refer again.

Surveying the limbs as wholes, we thus find them to be almost perfectly symmetrical, in respect of axes of direction of their several segments, flexions and extensions, reëntrances and saliences, and other superficialities. We have next to look more than skin-deep, in search of corresponding parts and organs. In this endeavor, it will be evident that neither form nor function has much to do with determination of homologies.† For shape, like size, is a thing of degree—of more and less—not of kind; and may vary interminably. Function is of course purely teleological, and therefore always represents special, not general, conditions; *e. g.*, the human sartorius is a peculiar flexor cruris; that of the bird is an extensor cruris. It will be found, of homologous organs, that "each in its turn plays many parts." Position and relation are the only safe guides. The law may be enunciated, that—

Corresponding parts are symmetrically disposed.

We will somewhat rapidly survey the bones, as an antecedent step to determination of the muscles; for identifications of the latter depend in greatest part

* *Fide* WYMAN, "*On Symmetry and Homology in Limbs;*" Proc. Bost. Soc. Nat. Hist., June, 1867, pp. 251-2; whence the following paragraph is complied in default of original investigations of my own.

* Really a teleological necessity; for without pronation of the forearm, the forelimb of quadrupeds would be useless for progression: since the hand, paw, hoof, flipper, or whatever special shape the extremity might assume, would point backward, and counteract the hind member; resultant of motion between the flexion and extension of the two limbs would be directly upward, not forward. So the forearm must be twisted around, through 180°.

† Having sufficiently indicated the difference between "homology," "homotypy," "antitypy," etc., I may, without danger of misleading the reader by ambiguity of language, hereafter use these words interchangeably, merely to avoid as far as possible monotonous repetition of expression.

upon those of the former. The bones are at once the soundings and bearings of the muscles.

No anatomists of note who adopt the idea of any sort of fore and hind correlation, now dispute the correspondence of the scapular and pelvic arches as wholes. All likewise agree that the main bones of the two—scapula and ilium—are antitypes. There is difference of opinion in respect of the other two of the three bones* that compose either arch. Owen holds coracoid and ischium to be homologous hæmapophyses; and consequently identifies pubis with clavicle. Clavicles and pubes may be hæmal spines, and be therefore homologous; but it is not determined that these are not also hæmapophyses; if so, we have choice of two hæmapophyses in each arch, one of which may be referred to either of the others. Wyman, from a different standpoint from Owen's (as far as can be gathered from his guarded expressions), makes no such special reference to the elements of a vertebra that these bones may form parts of, and determines, according to relative position alone, that the pubis is the representative of the coracoid, and the ischium of the clavicle. If it were clear that clavicles and pubes are hæmal spines, there would be no doubt in the case; but as it is, the dilemma is one of extreme difficulty. Wyman's identification is in accordance with the principle just laid down; clavicle being situate furthest forward, ischium furthest backward; coracoid and pubis respectively furthest backward and furthest forward. Yet I rather incline to the other view, with a proviso, as will be explained in treating of the muscles whose identifications appear to hinge upon this question.†

Regarded as symmetrical parts, the humerus and femur present no difficulty whatever; they are exactly correspondent. Various ingenious and profitless speculations, not necessary to particularize, have been wasted in the attempt to make them out to be serially or consecutively homologous, instead of reversely repetitive.

The patella is unquestionably a sesamoid, and therefore not an endoskeletal integer. No observed fact, nor valid analogical reasoning, supports the assumption of some, that it is a 'detached olecranon' from either tibia or fibula.

Various and curious views have been entertained respecting the homology of the bones of the forearm and leg: mostly based upon a presumption that these segments are 'serially' related. Both ulna and radius have been compared with leg-bones of the *opposite side* of the body: *parts* of either, again, have been referred to parts of tibia and fibula; &c. Such speculations, more amusing than instructive, merely require passing allusion; only two other views need be noticed. One of these is Owen's, and others'; —that the fibula repeats the ulna, and the tibia the radius. It is apparently based in some measure upon certain peculiarities in the contour of the head of the fibula of monotremes and marsupials; this bone there developing a great process resembling an olecranon; and, for the rest, upon some such fact as that, in the horse, *e.g.*, ulna and fibula are both reduced to mere anchylosed appendages of the radius and tibia, which alone bear, respectively, the fore and hind hoofs: so that here, apparently, radius = tibia. In the case of the horse, etc., it is merely development of corresponding bones of the two extremities in inverse instead of direct ratio; this is a teleological modification, not interfering with morphological homologies further than to obscure them. In some of the pedimanous mammals that develop perfect and movable leg-bones, the end of the fibula largely articulates with the astragalus, and the foot enjoys motion closely resembling, if not the same as, pronation and supination; here the fibula may "rotate" about the tibia precisely as, and nearly to the same degree that, the radius does about the ulna. If any morphological conclusions are warrantable from these conditions, they are as largely in favor of the view here advanced, as degradation of the fibula in the horse is for the contrary opinion. In the former case: it is as certain that the fibular fabella upon which stress has been laid is a sesamoid, as that the patella is one; nothing can be assumed from this. Again, the spatulous head of the fibula, in monotremes and certain marsupials, is not in subserviency to an extensor cruris, as the olecranon is to the extensor cubiti, but to the peroneal muscles that act upon the foot; it is not therefore even teleologically analogous to an olecranon, still less morphologically homologous. Once more; the ulnar olecranon is really all *shaft* (or 'continuity' of the bone) except a small epiphysis: in some mammals it is much more largely developed than in man; its posterior homotype is the "tuberosity of the tibia," or corresponding part of that bone; which in some birds, as, *e.g.*, *Puffinus*, *Colymbus*, *Podiceps*, et al., is prolonged into an immense "process" (so-called, but really continuation of the shaft) above the knee, giving extensive and highly advantageous insertion to extensores cruris. Adducing such facts as these is ploughing with an adversary's heifer indeed; nor need we galvanize a dead thing for the sake of killing it over again. In archetypal condition, neither of the four bones under discussion has any special development as to shape or function: the two of either limb are precisely similar parallel bones. Position is the only guide; the inner bone of the leg corresponds to the inner bone of the arm; the outer of the leg to the outer of the arm; tibia to ulna; fibula to radius. Comparative anatomy refuses to support the contrary surmise.

The tarsus so obviously repeats the carpus, that there is nothing to be said of these segments as wholes. Identification of individual bones of each, however, is difficult, if not impossible, in some instances. This is a consequence of the variable number (*e.g.*, two—tarsus of frog; eleven—carpus of armadillo; *fide* Wyman), shape, position, and function of the little bones. Form

* The student of human anatomy alone may require to be warned that his coracoid "process" is confluent not connate with the scapula, and therefore a distinct "bone," as it actually is in lower classes of vertebrates, as birds, *e.g.*, where it has sternal and scapular *articulation*.

† In respect of the nature of limbs, there are two conflicting and apparently irreconcilable theories. Owen modified Oken's idea that limbs are "liberated ribs," taking them as "diverging appendages" of certain ribs (*i.e.* of certain hæmal arches), and as "serially homologous" with the "oblique processes" that exist, *e.g.*, in birds. Thus the fore limb, in this view, is "an appendage" of the scapular arch, which is the hæmal arch of the hindmost cranial vertebra ("epencephalic"); and therefore an integral component of the archetypal endoskeleton. Wyman, on the contrary, does not consider limbs to be dependencies of the osseous framework from which they hang suspended—"their connection with the vertebral column through the scapular and pelvic arches is only secondary, as is that of the teeth with the jaws," he says; but as belonging to the category of tegumentary organs, as much so as the median fins of fishes. He continues: "The fore and hind limbs . . are outgrowths of the tegumentary cells, and for a time the cells undergo no differentiation into bones or other tissues. . . The bones do not, therefore, force the integuments out by their protrusion, but the integuments themselves have already grown out and the limb is formed, before the bones are developed" (*ibid.* p. 264). This is a view derived from embryological evidence afforded by observed *facts;* the former rests upon the theory of the vertebrate archetype: and embryology gives the more weighty and reliable data in the case. But whichever view be adopted for the limbs from heads of the humerus and femur outwards, the idea that scapular and pelvic are hæmal arches, and so parts of the endoskeleton, is not necessarily impugned. I think that Owen's remark to this effect has body: "Say that the appendage in Lepidosiren [*i. e.*, the pectoral limb—a mere filament] is a dermal development, and that the *humerus, radius*, &c., in its higher homologues, are skin-bones, and not parts of the endo-skeleton; it does not follow that the scapular arch . . is, also, a part of the dermo-skeleton." (*Comp. Anat. and Phys. Vert.*, III, p. 164.) So, if I am really called upon, in treating of muscles of the "limbs," to account for those that connect scapular and pelvic arches to the trunk, even the proven supposition that limbs are tegumentary outgrowths, and their bones therefore dermo-not endoskeletal, would be no obstacle in the way of the disposal of these muscles that I purpose to make.

and function, as we have seen, are no guides; though these seem to have been mainly relied on by some in this connection. In mammals, the bones occur under highly specialized conditions; and this is perhaps more particularly the case in man. Even articulation with the leg-bones may mislead! for in the mammalian foot, this is made by the astragalus alone; while in the reptilian, two or three bones may hinge upon tibia and fibula. Encountering these, and other difficulties that could be adduced, we can only rely, as so often already, upon position. There appears to be no sound alternative to regarding the carpal and tarsal bones as archetypically represented each by two rows of pieces of indeterminate shape, which are to be identified according to position. That is, the innner bone of the first tarsal row corresponds to the inner bone of the first carpal row, etc., (remembering that the forearm is supine, so that scaphoid is outside, pisiform inside, etc.).

This view, which will be followed, is Wyman's. But a question arises regarding the pisiform. Owen regards the os calcis as in itself repeating the cuneiform and pisiform together: mainly, it would seem, from teleological considerations; since the tuberosity of the os calcis (which=pisiform *sec.* Owen) and the pisiform both give insertion to what Owen regards as homologous muscles: viz., "flexor" carpi ulnaris and solæo-gastrocnemius. Wyman, in dissenting, shows that development of the calcaneum * does not bear out Owen's assumption that this bone is two in one; and is inclined to Cruveilhier's opinion, that the pisiform is a sesamoid. But he has just said (p. 268), that a sesamoid is "always detached;" whereas, the human pisiform is articulated with the cuneiform. The matter may be still open.

The five metatarsals clearly represent the same number of metacarpals; yet not in the order usually recognized, except in the case of the middle one (third); but inversely. For in the supine arm, the "first" metacarpal is on the outside, and the "fifth" metatarsal is therefore its correlative. So, also, the first metatarsal=the fifth metacarpal, &c. It may be observed in this connection, that when digits decrease in number, as in the transition from the unguiculate to the ungulate extremity, it is always the lateral ones that are successively removed: the third finger or toe is the only constant one. Its metacarpal or metatarsal is the one left, after the others have become functionless, or have disappeared.

The phalanges that are borne upon corresponding meta-carpals and -tarsals must be similarly correspondent. This proposition brings up again the difficulty before mentioned. Nothing is more certain than that thumb and great toe are *teleological* correlatives. They are on the same side of the limbs in the prone (*i. e.* teleological) position of the forearm; both are largest of the digits; both divaricate from the parallelism that the other digits preserve; both have most independent movement; and especially, both are bi- instead of tri-articulated, while the other digits have three joints. But it must be remembered that the usual position of the thumb has been proven to be morphologically false; while the size, shape, and function are certainly not infallible criteria, and therefore not decisive arguments in this connection. We have here an instance of extreme specialization; of teleological modification so profound as even to change the number of segments. In man, that is; but in some animals a "thumb" is no more a thumb in respect of any function it has, than a little finger is; and the same may be said for any of the thumb's apparent peculiarities. In idea, the several digits of either extremity are identical in size, shape, position, and construction; differentiation in either of these respects is a subsequent adaptation. For some reason unknown, it is best for mammals, that the *inner* one of the terminal segments in either limb (in the customary prone position of the forearm) should differ from its fellows, in the points above mentioned; whence occurs the physical resemblance, carried even to number of internodes, of the thumb and great toe. Yet outer digits must be regarded as antitypical of outer digits, and inner of inner. The thumb must be held to be correlated with the little toe; the great toe with the little finger; and other digits in the sequence indicated by corresponding metacarpals and metatarsals (index with "fourth" toe, etc.).

The foregoing appear to be the principal considerations that need be here presented in preparation for the discussion of the muscles that will be begun in our next. Reference to Prof. Wyman's paper will show even more clearly than our frequent citations may have indicated, how closely we have trodden in that anatomist's footsteps in drawing osseous correspondences—not blindly, however, as may be apparent; but unable not to see the validity of arguments adduced, and appreciate the reasonableness of views advanced. The following identifications of special bones, which have been adopted for this essay, are his, queried in two instances:—

THE CORRESPONDING BONES OF THE LIMBS.

Fore.	*Hind.*
Scapula.	Ilium.
Coracoid.*	Pubis.
Clavicle.*	Ischium.
Humerus.	Femur.
Ulna.	Tibia.
Radius.	Fibula.
Pisiform.	——?
Cuneiform.	Scaphoid.
Semilunar.	Calcaneum.
Scaphoid.	Astragalus.
Unciform.	Entosphenoid.†
Magnum.	Mesosphenoid.†
Trapezoid.	Ectosphenoid.†
Trapezium.	Cuboid.
Metacarpals.	Metatarsals.‡
Phalanges.	Phalanges.‡
(Pollex.	(Digitus minimus.
Digitus minimus.)	Hallux.)

REMOVING SUBSTANCES FROM THE EAR.—*The Dental Office and Laboratory* recommends the following method for this purpose:—Warm a little adhesive plaster of the best quality, and place the end of a probe in it, so that there will be a pretty large collection of the plaster, of a globular shape, about the end of it. When it is cool, place the patient in a proper position, again warm the plaster and introduce it to the substance, to which it will adhere. Poising the probe upon the fingers until the plaster is cool, make gentle traction until the body is brought out. The operation is seldom attended with pain.

* "In its mode of ossification, except in the development of a thin scale on the end of its tuberosity, it follows that of the other tarsal bones, viz., from a single centre." (*l.c.*, p. 275.)

* Should these change places in the table?

† There is need of a single word for each of these bones. Owen's are hybrids ("entocuneiform," etc.). The above will not conflict with cranial elements.

‡ Each to the other in reversed direction from that in which they are usually numbered.

RADICAL CURE OF "INGROWING NAIL."

By C. W. TRUEHEART, M.D.,

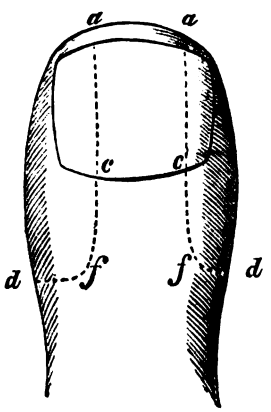
OF GALVESTON, TEXAS.

The operation advised by many of the text-books on surgery for the cure of this intractable and exquisitely painful and troublesome affection—that by slitting the nail through longitudinally, and then tearing away the whole or the lateral offending portions—is, I believe, notoriously ineffectual. During the weeks, or even months, that elapse ere the formation of the new nail, the patient is greatly incommoded in wearing a shoe or walking, by the extreme sensitiveness of the unprotected toe; and the new nail is generally as faulty in its growth as the one removed.

The plan of treatment by scraping the centre of the nail down to the quick (or cutting out a V-shaped piece), and then elevating the edges of the nail by pushing lint under; and that by drawing the impinging soft parts away from the edges of the nail, by means of adhesive strips, are well suited for the relief of the less aggravated of that class of cases due to an encroachment and excessive pressure of the soft parts upon the nail, but are quite inadequate for the cure of the more severe cases, especially where there is an abnormal width of nail, congenital or acquired.

A little method of operation which I have resorted to with most satisfactory results in six out of eight very severe cases in which it was made, and which, though it has doubtless suggested itself to, and perhaps been done by others, I fail to find mentioned in any of a considerable number of surgical works and periodical literature consulted, may perhaps prove of interest and value to the profession. It consists in the removal of the lateral offending portions of the nail, and the *thorough* extirpation of the matrix pertaining thereto; the central half or two-thirds of the nail being preserved intact, to serve its function of protecting the toe.

The patient should be anæsthetized. An incision, *c f d*, is made on one or both sides of the toe (as the case may demand), extending back six or eight lines towards the foot, care being taken to avoid opening the adjacent joint of the toe. A thin flap, *c f d*, of integument, including as little as possible of the matrix, is dissected up. The sharp-pointed blade of a straight scissors is thrust under the nail, cutting it through from *a* to *c*; and the strip of nail thus detached, with the tissue beneath and at its root, *carefully* and *thoroughly* dissected out, down to the very periosteum, so as to include all the matrix concerned in the development of that portion of nail.



The flaps should be brought together by adhesive strips. Any excess of granulation present having been pared off, the integument on the lateral aspects of the toe should be drawn over to the newly established edge of the nail, so as to cover the wound surface made by the excision of the nail, and held in place by adhesive strips. To facilitate this, it will in some cases be advisable to dissect up the integument on the side of the toe for a few lines.

Where much inflammation of the parts exists, it is decidedly best to reduce it before operating; and this is most effectually and quickly attained, and with least loss of time to the patient in the end, by a few days' rest in the recumbent position, elevation of the foot, with the use of cold lotions, etc.

In the cases referred to above, the patients were able to walk about and wear a loose shoe with comfort in six to ten days. The two cases of failure were due to an incomplete extirpation of the matrix.

VIENNA, March 1, 1870.

MEDULLARY CANCER OF THE SPLEEN.

DISEASE OF THE SPLEEN AS A CAUSE OF INTERMITTENT CHILLS.

By PAUL R. BROWN, M.D.,

LENOX, MASS.

JANUARY 1st, 1869, we were called to see Wm. Fields, a colored man, 60 years old. Inquiring into the previous history of the case, we ascertained that about the 1st of April, 1868, he was taken ill with a disease which the attending physician called intermittent fever. He presented at that time every symptom of this disease. The ague was tertian in its character. The chill was well marked, and followed by high fever. During the febrile excitement he was sometimes delirious. After the fever came the sweating stage, accompanied by great depression. For a few weeks previous to this attack he had an "uneasy feeling" constantly in the splenic region. At that time he was attended by Dr. Rising, of New Marlboro, Mass. The doctor prefaced his treatment by mercurials, and followed it up with large doses of quinine. This treatment, to some extent, abated the periodicity of the attacks, as the patient would go for a week or ten days without a paroxysm. We found the patient with similar symptoms to those above mentioned. The ague had gone back to the tertian form. He was somewhat emaciated; countenance, as far as we could judge, cachectic; appetite good; strength fair; pulse 104. We did not examine the case very thoroughly at our first visit, and diagnosed it as intermittent fever. We gave him a mixed cathartic followed by large doses of quinine. At the end of two weeks the intermission was four days. We then gave him Fowler's solution, with no apparent effect. On the 5th of February, 1869, the patient complained of pain and tenderness in the splenic region. We continued the quinine two weeks longer with no apparent effect. We then began to suspect that we had made a false diagnosis, and examined the case thoroughly. Auscultating the lungs, we found them healthy, and also the heart's action normal. The stomach we judged to be in a comparatively healthy state, as his digestion and appetite seemed to be good. We examined his urine microscopically and found nothing abnormal. S. P. 1015. We then diagnosed the case by exclusion to be malignant disease of the spleen, although the diagnosis could not be positive. The patient gradually lost flesh, strength, and appetite. The intermittent fever continued unabated. The patient became very much emaciated towards the end of life. He continually complained of pain in the region of the spleen. He finally died of exhaustion on the 10th of July, 1869. During the last two or three months we simply used palliative treatment, such as anodynes and tonics. We were allowed to perform a partial post-mortem, after a great deal of opposition. We made it one day after death. Cadaver very much emaciated. Rigor mortis, well marked. The

lungs were healthy, save a slight pleuritic adhesion. Heart remarkably free from disease. Stomach and liver healthy, although very much emaciated. There was a very small amount of fluid in the abdominal cavity. The omenta were excessively thin. The intestines and bladder seemed to be sound. There was some slight congestion of the right kidney. The spleen was the grand centre of disease in the present case. This organ was a third larger than it should have been, was quite white in color, and faintly streaked with pink lines. It presented a peculiar nodulated appearance, and was very firm and elastic to the touch. Upon making a section, we found it to be a perfect specimen of "firm medullary cancer," as defined by Paget.

The whole organ presented the following appearances to the unaided eye: Its color was a pinkish white, its structure homogeneous, and tearing apart with some slight degree of force. Upon pressure, a thick, creamy fluid exuded. The whole substance seemed to present the same characteristics. Dr. Frank K. Paddock, of Pittsfield, Mass., formerly Professor in the Berkshire Medical College, and myself examined a portion of the organ microscopically. We found it to consist of masses of nucleated cells, imbedded in a stroma, which was fibrous in its appearance. The Malpighian corpuscles were obliterated. Free nuclei, more nearly resembling spermatozoa, were seen floating about in the cancer-juice. The history of the case, the post-mortem and microscopic examinations, warrant us in saying that our diagnosis of malignant disease of the spleen was correct.

The peculiar point in the case was the well-marked paroxysms of intermittent fever, occurring in a patient living in a region free from all malarial influences, and who, moreover, had always resided in a hilly and mountainous country, free from even a suspicion of malarial disease. It has seemed to us that probably in cases of intermittent fever, when the spleen is sensibly affected, the disease of the spleen is the cause of the fever, and not the contrary, as has been hitherto taught. The delicate capillary plexus surrounding the Malpighian corpuscle is undoubtedly the source whence they derive their contents. The splenic veins, so intimately connected with these corpuscles, at certain times become the carriers of their contents into the circulation, to a greater or less extent. The immense size of the arteries and veins in this so-called "ductless gland," proves that this organ holds an important place in the human system. It may not be an incredible thing, that any excessive derangement of the functions of this organ may produce intermittent symptoms in the human economy; that intermittent fever, instead of being the *cause* of splenic enlargement and disease, is simply a sequence. To have intermittent fever, it has hitherto been supposed that we must have the blood contaminated by miasmata which have their habitat in certain regions. This undoubtedly to a certain extent is true, but does this contamination *alone* produce the specific disease called intermittent fever? We think not. We claim that derangement of the functions or textural changes of the spleen are the invariable causes of intermittent fever, whether the derangement of functions or structural changes are produced by miasmata present in the atmosphere, food, or water; by the fumes of melting zinc, or by the infiltration of cancerous matter into this organ. Miasmata entering the circulation may be carried along until they enter the splenic arteries; then passing through the capillary plexus surrounding the Malpighian corpuscle, by endosmosis become a part of its contents. By some zymotic process, these may increase to such an extent that the nutrition of the corpuscle becomes defective, and the whole spleen is disordered in its functions. The splenic veins convey from this ill nourished corpuscle more or less of this materies morbi into the circulation, which thus becomes contaminated, and intermittent fever is the result. The intermittent fever, so well marked in our patient, who died of medullary cancer of the spleen, was undoubtedly caused by the infiltration of cancerous matter into this organ from the blood, or, from some cause unknown, the nutrition of the organ became defective. Malnutrition of any organ must be the cause of functional derangement and pathological changes in its tissues, however that malnutrition may have been induced. Finding a soil well fitted to nourish its malignancy, the cancerous process went on until the functions of the organ were destroyed. They could not be replaced, and death was the result. The gradual derangement of the functions of this organ produced the intermittent fever, which increased in violence to the end. In this case, did the intermittent fever produce the cancer of the spleen, or *vice versâ*? We think it did not. A patient free from miasmatic influence of every kind is stricken down by intermittent fever, and finally dies of cancer of the spleen. What produced the fever, if not the malnutrition and resulting disorder of the function of this organ? We cannot explain this case otherwise, and from analogy and the general history of intermittent fever we assert that malnutrition of the spleen is the exciting cause of this disease. We hope this case may turn the attention of the profession more directly to this subject, and that greater light may be thrown upon the functions and diseases of the spleen.

Progress of Medical Science.

Cardiac Complication of Renal Disease.—Dr. Murchison calls attention to two cases of cardiac disease under treatment, in both of which the aortic valves were affected. He expressed the belief, founded on observation, that in cardiac disease following morbid changes of the kidneys, the aortic valves were the first affected, and oftentimes were the only ones involved, while, on the other hand, acute rheumatism was most often followed by mitral diseaseoas the initial affection.—*Richmond and Louisville Med. Journal.*

Cases Treated by Hydrate of Chloral.—Surgeon A. M. Adams reprints in the *Lancet* two cases relieved by hydrate of chloral. A delicate female was delivered of her first child, and four days afterwards was attacked with acute, ungovernable, puerperal mania. Bromide of potassium, opium in large dose, and chloroform were given without benefit. Forty grains of chloral were given several hours after the discontinuance of the other remedies. At this time the pulse was scarcely perceptible, and the extremities cold. In five minutes after taking the chloral she became calm and conscious. Soon after drowsiness was followed by sleep, which later was at first rather profound, but soon became natural and light. The attacks of mania recurred, and each time the chloral, in from forty to sixty grain doses, was followed by a natural sleep lasting from six to eight hours.

The other case was of a man laboring under a severe attack of asthma. Previously chloroform had been frequently employed to cut short the attacks, but with only temporary relief. Thirty grains of chloral were given, and in less than twenty minutes calm sleep was induced which lasted for eight hours.

Improved Formula for Chalk Mixture.—To obviate unpleasant and dangerous souring of chalk mixture as commonly prepared, glycerine may be substituted for the sugar, according to the following formula:—℞ Cretæ Preparat., Glycerini, āā ʒ ss.; Pur. G. Acaciæ, ʒ ij.; Aq. Cinnam., Aquæ, āā ʒ iv. Rub well together until thoroughly mixed. This mixture will keep during a whole summer. The glycerine exerts a positively soothing effect upon the bowels, as well as in some degree arresting fermentation.—*Boston Journal of Chemistry.*

Preservation of Anatomical Specimens.—The process of M. Von Vetter:—Add to seven parts of glycerine at 22° one part of raw brown sugar and half a part of nitre, till there is a slight deposit at the bottom of the vessel. The portion to be preserved is then plunged in dried or not dried, and left in the mixture for a time proportioned to its dimensions. A hand, for example, should remain eight days in the liquid; when it is taken out it is stiff as a piece of wood, but if it is suspended in a dry and warm place the muscles and articulations recover their suppleness.—*Detroit Review of Medicine and Surgery.*

Chloral.—*The Gazette des Hôpitaux* reports a case in which chloral was exhibited to the extent of perfect anæsthesia, under which amputation of the leg was performed by M. Noir. After the operation it was long before the patient recovered his sensibility, and the symptoms were most alarming—coma succeeded by delirium, vomiting, and prostration.

Death from Injecting Perchloride of Iron in Sanguineous Tumors.—A child, ten weeks old, having three sanguineous tumors respectively on the left cheek, left leg, and right lumbar region, was brought to Prof. Santesson, of Stockholm. Having decided to employ subcutaneous injections, he proceeded to use a liquid composed of ferri perchloridum six parts and alcohol one part. The injection was made with a glass syringe containing eight or ten drops of the mixture. By the first injection half of the contents was used, the needle withdrawn, and reintroduced and directed deeper into the tumor. Before the second injection was completed the operator was obliged to cease on account of threatening symptoms, and death of the child took place in about two hours. The autopsy revealed the following symptoms:—Tumor much lessened in size, its tissue firm and solid from coagulation of blood. The surrounding veins were empty. The external and internal jugulars contained no clots in the superior portion, but as they approached the chest the contained blood was generally clotted. The clots became more and more firm in the subclavian, the superior vena cava, and in the right cavities of the heart. These were literally distended with coagulated blood. The left auricle contained a small clot, the left ventricle was empty. It is probable that in introducing the tube the second time one of the veins was penetrated.—*Detroit Review of Medicine and Pharmacy.*

Excision of Joints.—In Mr. Gant's paper at the Royal Medical and Chirurgical Society of London, on April the 12th, the author defined *incurability*, as regards excision, to be "that condition of the local disease wherein the joint has become functionally useless by destruction of the articular cartilages, without the supervention of anchylosis, but while the constitution still retains the reserve power requisite for the long process of reparative union—averaging three months after removal of diseased bone." With regard to results, excision proved successful in sixteen out of twenty cases of knee, hip, and elbow. Re-excision was resorted to in two of the four cases; one knee-joint and one elbow-joint, the latter successfully; and secondary amputation was performed in three of the four cases, all of which did well. No death occurred in any of the operations. Mr. Wood said that in King's College Hospital it is now the practice to employ a single straight incision across the front of the joint, level with the top of the tibia. The greatest modern improvement in the practice of excision was, Mr. Wood observed, the method of gouging away the diseased bone, and leaving the periosteum and the attachments of muscles undisturbed. Mr. Holmes does not agree with sub-periosteal resection.—*Medical Press and Circular.*

Substitute for Quinine.—An Italian correspondent informs us that Signor Pavia has extracted from the leaves and roots of the box (*Buxus sempervirens*) an alkaloid, which he calls buxina, that has been found most efficacious in a large number of cases treated by seven different Italian physicians. It is in the severe intermittent fevers that prevail in the marshy parts of Italy that the new drug has been put to the test. Out of six hundred and eight cases submitted to the new alkaloid five hundred and thirty-five were completely cured—nearly eighty per cent.—enough to permit the claim for it as a specific being entertained.

In a single dose of fifteen grains *sulphate of buxine* generally prevents the next paroxysm from appearing. In a few cases it only diminishes the intensity of the paroxysm. It is only in rare cases that a second dose has had to be given. The drug seems effectual in every type of disease attributed to marsh miasms.—*Medical Press and Circular.*

Sponge Tents.—An expeditious and simple mode of preparing tents, tampons, &c., of compressed sponge, is the following:—Moisten the sponge thoroughly, and then having pressed out the excess of water, mould it to the required form, either with the fingers or packing in a suitable mould, and immerse immediately in strong alcohol. In a few minutes the sponge sets or hardens so as to retain its shape permanently on removal of pressure. As soon as the alcohol has evaporated it is ready for use. A few drops of water restore it to its former shape.—*Detroit Review of Medicine and Pharmacy.*

Arseniate of Antimony for Asthma.—We are informed by one of our foreign correspondents that in Spain the use of arsenic is more common than with us, and that arseniate of antimony is becoming extensively used in the Peninsula as a remedy for obstinate asthma. It may be advantageously given in pills, combined with muriate of morphia. The dose to commence with is two milligrammes, and this may be cautiously repeated up to five doses a day. The drug is also administered by inhalation, cigarettes being smoked which have been prepared for the purpose. The smoker should keep the smoke in his mouth as long as possible. The treatment should be sometimes suspended for a time, and in recommencing it, it is necessary to begin with the smallest dose, and proceed as cautiously as on the first occasion of employing it. It is believed by the profession in Spain that arsenic not only acts through the nervous system, but has a special effect on the walls of the pulmonary air-cells, restoring to them their elasticity.—*Medical Press and Circular.*

Dr. Dalby on Perforations of the Membrana Tympani.—Dr. Dalby says it may be stated generally that the existence of perforation is not the cause of deafness, but that such is to be looked for in the middle ear. There are slight thickenings of the lining mem-

brane of the tympanum, or the membranes covering the ossicles, etc., or caries of the little bones and labyrinth. When the tympanum becomes congested, the swelling of its mucous lining soon closes the Eustachian tube; and its secretions having no other exit than through the membrane, perforations are continually kept open, or, after closing, are reopened by the pressure of discharge. The principle is to cleanse the ear well, first with an ordinary syringe, and then a syringe is used with a nozzle fitting the meatus, and defended by a piece of india-rubber tubing. In this way alkaline solutions are sent along the tympanum and Eustachian tube, passing out through the nose. Afterwards astringent solutions are injected, such as five grains of sulphate of zinc to the ounce.—*Med. Press and Circular.*

INSANITY CAUSED BY SYPHILIS.—Prof. Joseph Jones, M.D., New Orleans, La. (*The N. O. Journal of Medicine*), corroborates the assertions of those investigators who maintain that the brain may be directly affected by syphilis; the nervous substance being the seat of syphilitic gummy deposit followed by softening; and cases have been recorded in which white and red softening of the cerebral substance have been caused by syphilis. In the neuralgic affections, paralysis, epilepsy, and dementia, following the appearance of the constitutional effects of syphilis, good results and even effectual cures may be obtained by the judicious use of the bi-chloride and bin-iodide of mercury and the iodide of potassium. One-sixteenth of a grain of the bi-chloride or of the bin-iodide of mercury has been administered in his cases in Charity Hospital, N. O., in combination with iodide of potassium three times daily. In the severest cases of nervous derangement the iodide of potassium has been used freely, in doses varying from one to two scruples three times daily.

CASES OF NERVE-IRRITATION CURED BY SURGICAL OPERATIONS.—John H. Packard, M.D., of Philadelphia (*Am. Jour. Med. Sciences*), narrates three cases of nerve-irritation; in all the operations resorted to gave complete relief. In one of these cases there was irritation of the terminal filaments of the median nerve at the side of the last phalanx of the thumb; in the second, the trunk of the infra-orbital was the seat of the trouble; in the third, the cerebrum itself was pressed upon. The *third* case was that of a boy, æt. 14, who had a very large portion of the scalp torn off the top of the head by the discharge of a shotgun, together with a patch of periosteum about two inches square; there was also a fissure of the bone, stellate, two of the cracks branching out an inch or more, forming an acute angle with one another. On the sixth day, finding that there was a spot at the apex of the angle between the two fissures, pressure upon which induced convulsions, he applied the crown of a trephine at that point, and removed a button of bone. This case was, in his opinion, remarkable from the extreme severity of the lesion, the sudden onset on the sixth day of very grave symptoms, and their speedy disappearance after an operation which, although indicated and even demanded, seemed scarcely adequate to the production of benefit so immediate, so complete, and so permanent.

FRACTURE OF THE CLAVICLE TREATED BY POSITION ONLY.—Dr. M. S. Jones, of St. Louis, Mo. (*The Med. Archives*), relates a case of fracture of the outer third of the left clavicle successfully treated by position only. The treatment consisted in confining the patient on his back, with a pillow between the scapulæ, no appliances being made other than an ordinary sling, which held the hand in position across the chest. This arrangement was found to secure good position across the chest.

THE CAUSE OF DIPHTHERIA.—Dr. Spinzig, of St. Louis, Mo. (*The Med. Archives*), does not coincide with a writer in *Virchow's Archives* in the belief that the cause of this affection is a fungus which destroys the mucous membrane. The fungus he imagines a consequence or concomitant, rather than a cause of the disease.

OBSTINATE GLANDULAR ENLARGEMENT.—Jos. Adolphus, M.D., Des Moines, Iowa (*Chicago Med. Times*), recommends this formula in a case of obstinate glandular enlargement: ℞. Ipecac, ʒ ss.; Podophyllin, gr. v.; Quinine, gr. xv. Make into thirty pills, one three times daily.

TINCTURE OF CANTHARIDES IN CEREBRO-SPINAL MENINGITIS.—Dr. Thos. C. Murphy, Grand Valley, Ill. (*Chicago Med. Journal*), believes that tinct. cantharides is of great value in this disease, from its stimulant effects, in cases where there is great depression of the nervous system. He states that the credit of reviving this remedy is due to Prof. J. Adams Allen, of Rush Medical College.

A RARE CASE OF DISLOCATION OF HUMERUS.—T. A. Montgomery, Mankato, Minn. (*Chicago Med. Journal*), publishes the following case of fracture: While a man, æt. 50, was carrying wood up a flight of stairs, he fell backwards, striking his weight on his right hand and arm, which he had thrown behind him to break his fall. On examination, the injured shoulder appeared somewhat higher than that of the opposite side. There seemed to be an unnatural prominence of the acromion, with a hollow under it, at the back of the joint; also an undue fulness in front. The diagnosis was partial dislocation of the humerus, upwards and forwards; the head of the bone lying against the coracoid process. He has failed to find more than two instances of this dislocation, either in the text-books, or in any journal of medical or surgical science.

ON MASKING THE NAUSEOUS TASTE OF EPSOM SALT.—Isaac W. Smith, of Phila. (*Proceedings Am. Pharmaceutical Asso.*, 1869), after giving the subject considerable attention, obtains the most satisfactory result by combining Epsom salt with a strong infusion of liquorice root, and evaporating to dryness. The following is his process: Take of liquorice root, contused (deprived of outer bark), four troy ounces; boiling water, two pints, or sufficient.

Mix and allow to stand, with occasional stirring, until cold; then press through muslin, adding more water if necessary, until the residue no longer tastes, then filter; to the filtrate add Epsom salt, four troy ounces, and evaporate to dryness over a water-bath. Each ounce of the compound represents about one ounce of the crystallized salt.

CINCHO-QUININE CONDEMNED.—W. T. Wenzell, a chemist of California (*Pacific Med. and Surg. Journal*), lately read a paper on Cincho-Quinine before the California Pharmaceutical Society, and arrived at the following conclusions: This agent, although having the advantage of being nearly tasteless, does not contain quinia, quinidia, and cinchonidia, and therefore does not represent the whole of the active principles of the bark. It cannot exert the full effects of sulphate of quinia in the same dose, inasmuch as the stated dose of "Cincho-Quinine" is from five to thirty grains.

A SIMPLE WAY TO OBTAIN OZONE.—Behind the short flame of a Bunsen burner a large beaker is placed with

the opening to a flame, and a current of air, by means of a glass or any other tube, is blown through the flame right into the mouth of the glass. This, after a few seconds, is covered with a glass plate, on removing which the characteristic odor of ozone will be at once perceptible. Starch and guaiac paper will give a decisive reaction.—*Drug. Circ. and Chem. Gazette.*

COLORLESS TINCTURE OF IODINE.—A correspondent of *The Druggists' Circular and Chemical Gazette* sends a formula for a colorless tincture of iodine, which is used with a great deal of success. Take:—

Tinct. iodine ..... ʒ j.,
Water of ammonia, concent..... ʒ ij.,
Carbolic acid—"Calvert's,".....gtt. viij.

LORING'S OPHTHALMOSCOPE.—Edward G. Loring, M.D., Surgeon to the Manhattan Eye and Ear Hospital, New York (*Am. Jour. Med. Sciences*), publishes an interesting paper on "Determination of the Optical Condition of the Eye by the Ophthalmoscope," with cuts of his modification of the ophthalmoscope. In this instrument, detachable cylinders are substituted for the fixed Rekoss disk, now common to a number of ophthalmoscopes. But three cylinders are generally employed, though these might be multiplied indefinitely were there any occasion for so doing.

Those who are desirous of obtaining this instrument can address the maker, H. W. Hunter, Optician, 1132 Broadway, New York City.

PUERPERAL CONVULSIONS FROM "NEPHRITIS" SUCCESSFULLY TREATED BY MORPHIA HYPODERMICALLY.—Dr. R. B. Bonticou, Troy, N. Y. (*N. Y. Medical Journal*), recently administered morphia hypodermically to a woman, 35 years of age, with puerperal convulsions, with success.

He says in concluding, this is the second case within a year in which he has used morphine, with satisfactory results, in convulsions occurring before labor from nephritis, in both instances inducing labor with the douche, and saving both mother and child. Two other cases came under his observation lately, where convulsions, occurring during and after labor, were promptly controlled by the use of morphine hypodermically.

THREE CASES TREATED BY HYPODERMIC MEDICATION.—F. D. Lente, M.D., Cold Spring, N. Y. (*N. Y. Medical Journal*), writes to Professor George T. Elliot, M.D., and enumerates three cases relieved by *hypodermic medication* (morphia). The *first* was the terrible headache succeeding the chill in intermittent fever; the *second*, a case related by Professor Alonzo Clark, M.D., before the New York Academy of Medicine, May 9, 1866, when fifteen drops of Magendie's solution were injected into a lady patient, with a cold, moist surface, vomiting, and copious dejections,—"restless, nearly pulseless, and apparently dying,"—nothing else could be borne, and after the lapse of fifteen minutes the vomiting ceased, the pulse returned, and a gentle slumber was induced, which lasted for two hours. Dr. L. remarks, What other antidote can equal this? The *last* was a case of sporadic cholera, and when visited the patient was cold, clammy, with dusky surface, cold tongue &c., &c. Three-quarters of a grain of morphine was injected, and, strange to say, another dose was not required. Professor Elliot was the first to suggest the use of the hypodermic method publicly in this country, and had the first American instrument manufactured, in August, 1857.

TO INDUCE DIURESIS IN URÆMIA OF SCARLET FEVER.—C. H. Routh, M.D., Phys. to the Samaritan Hospital (*London Med. Mirror*), in cases of renal congestion advises counter-irritation over the loins, in addition to the warm bath. He is disposed in his next case to try the effect of a foxglove leaf poultice, as, from the evidence of others who have tried it, it has been found effective in inducing diuresis. He has used extensively tr. digitalis in full doses, combined with small doses of tr. lyttae. For an adult, ʒ j. of the former to 10 or 20 of the latter, repeated at intervals of 4 hours 3 or 4 times. Dr. R. has seen these agents in this combination act so well, that he knows of no other remedies which he would sooner give in these cases.

TREATMENT OF RHEUMATISM.—M. G. de Mussy (*Paris Corr. Med. Press and Circular*), at the Therapeutical Society, gave an account of his success in the treatment of rheumatism by a combination of colchicum with bromide of potassium. This practitioner has long employed tincture of seeds of colchicum in articular rheumatism, and it generally removes the fever in a few days. When he first added to this the bromide, he found not only relief to the febrile symptoms, but a calm sleep, never disturbed by the dreams that opiates often produce. He gives the tincture in doses of 15 to 20 minims—occasionally even to 30—but never exceeding that last dose, so as to avoid intestinal irritation.

In sub-acute cases M. de Mussy employs, in addition, iodide of potassium or quinine, according to the constitution of the patient, and afterwards a course of arsenical baths.

ETIOLOGY OF EPIDEMIC DISEASES.—W. P. Thornton, M.D., Cincinnati, Ohio (*The Cin. Lancet and Observer*), in an article on "Etiology of Epidemic Diseases," believes that the so-called period of incubation, common to most contagious diseases, is but the period required for a sufficient cell-growth, after its implantation in the new soil, to produce disease. Therapeutical experience also confirms this theory. No intelligent practitioner believes it is in the power of man to cut short scarlatina, small-pox, measles, typhoid fever, or Asiatic cholera. All we expect to accomplish is, by judicious hygienical and therapeutical means, to obviate those *secondary* local affections which may prove fatal to the lives of our patients; but over the essential process itself we have little control.

He therefore concludes that all epidemic, contagious, and infectious diseases are propagated by cellular implantation into the circulation or on the surface of the human body, where, after a period of time requisite for multiplication and growth, they produce disease.

This is different from the so-called animalcular theory, inasmuch as that only *a cell*, be that animal or vegetable, is necessary to produce the morbid process which we call disease.

DOES ALCOHOL WARM THE BODY?—Prof. Bing (*The Practitioner*) has come to the following conclusions on this subject: 1st. That alcohol lowers the heat of the body, and that it preserves life in febrile affections, where the temperature rises very high, by its antipyretic properties. 2d. That extreme depression of the vital powers in febrile cases is most frequently dependent upon the temperature of the blood, and passes off when it falls. 3d. That the number and strength of the contractions of the heart always rise under the use of alcohol. Whenever, therefore, such an effect would be injurious, alcohol would be an improper remedy. 4th. That in all probability alcohol lowers the temperature by the retarding influence it exerts over the oxidizing process.

OSBORN'S NEURALGIC PILL.—T. C. Osborn, M.D., Greensboro, Ala., writes to the editors of the *New Or-*

leans Journal of Medicine, that the subjoined combination is very effectual in cases of neuralgia: ℞. Zinci cyanuretum. gr. vj.; quiniæ sulphas, gr. ix.; morphiæ sulphas, gr. iss.; ext. belladonnæ, gr. iij. Ft. pilulæ No. vj. S. One pill every 6 hours, until the pain is relieved.

Treatment of Spermatorrhœa from Self-Pollution.—Dr. J. Waring Curran, Osman House, Sutton, Wilts. (*London Med. Mirror*), finds it is absolutely necessary to make a sore in the penis. Most of these patients have a long prepuce, and he selects the mucous surface of it for the production of a small sore with an irritant caustic. The evil habit is seriously broken in upon thereby, and masturbation for a time successfully baffled. Bromide of potassium is given in full doses internally, and the oxide of zinc in two grain doses twice daily, with a camphor and conium pill at bedtime.

Heat and cold are applied alternately to the lower part of the spine, with a dash of cold water night and morning to the genitals. Dr. W. enjoins a generous regimen, avoiding stimulating beverages, and recommends active habits and open air exercise; the patient is advised to retire for the night greatly fatigued, to sleep upon a hard bed with light coverings, and to arise in good time in the morning.

Bismuth Sub-Nitrate in Aiding the Digestion of Cod Liver Oil.—J. Adolphus, M.D., Des Moines, Iowa (*Chicago Medical Times*), finds that stomachs which defiantly resist every effort made to coax them to retain cod-liver oil, or digest it, are made to yield by administering sub-nitrate of bismuth, in 10 gr. doses, four times daily, in connection with the cod-liver oil.

Bismuth has not the power of pepsin. Its action is on the nutrition of the mucus as nervous tonics of the stomach, allaying irritation, quieting hyperæsthesis, relieving engorgements through the former operation, and allowing the stomach to secrete a more healthy fluid and retain its contents with greater ease and quiet. Bismuth he believes is a great aid to the digestion of cod-liver oil in this way. Many cases may be overcome by pursuing this simple course. As to the cod-liver oil, Dr. A. finds Parker's the best.

Treatment of Malignant Pustule.—Dr. Caspar, of Stassfurth, asserts that he has treated several hundred cases of malignant pustule successfully by strong solution of ammonia, and that all the patients recovered except one—a pregnant woman, whose stomach rejected everything. The dose for children was one, two, or three drops, and for adults four drops, given every hour, day and night, with sweetened water. This treatment must be continued until the inflammation ceases around the pustule.—*N. Y. Med. Journal.*

Tartar-Emetic Treatment of Nævus.—Mr. Bateman, in the *Lancet*, calls attention to the tartar-emetic plaster for the cure of this class of tumors, after having employed it successfully for fifteen years. The formula is ant. of pot. tart., 1 part, ung. resinæ, 2 parts; to be spread on thin leather or linen. When the skin is not easily blistered, or the nævus is thick, equal parts of the two ingredients must be used. The pustulation must be repeated again and again until the tumor sloughs. By this means one case—a child with twenty-five nævi on various parts of the head, trunk, and extremities—was cured.—*Richmond and Louisville Medical Journal.*

Sulphite of Soda in Erysipelas.—Dr. George Kelmer bears the following testimony:—A patient, aged 30, was attacked with erysipelas, which involved the right hand and arm, extending nearly to the shoulder. They were swollen, tense, and hard, with one or two patches which assumed a decidedly gangrenous character; pulse 120; respiration hurried; skin hot and dry; tonsils dark red, swollen; urine scanty and high colored. Patient was ordered three grains of quinine every three hours, with a teaspoonful of the following mixture intermediated:—℞. Sodæ Sulphitis ʒ j., ext. glycyrrhiz. ʒ i.; aq. font. ℥ ij. As a local application, an ounce of the sulphite dissolved in a quart of water and applied on cotton over which rubber cloth was applied. Beef-tea freely, with good ventilation. At the end of one day there was a marked improvement, and the patient was soon convalescent.—*Western Journal of Medicine.*

Repeated Bilateral Lithotomy in a Child.—Dr. Louis Bauer reports the history (*St. Louis Med. and Surgical Journal*) of a boy four years old, upon whom the bilateral operation of lithotomy was twice performed, several calculi of various sizes being removed at each operation. Symptoms of calculi being again exhibited, and fearing the consequences of a third operation and finding them composed of the triple phosphate, he used tri-weekly injections of one part of dilute nitric acid and seven parts distilled water. The fluid was kept back in the bladder for about half an hour, and afterwards the bladder was thoroughly cleansed with warm water. The acid injections producing no perceptible irritation of the bladder, the fluid was allowed to remain as long as the patient could bear it. The internal administration of nitro-muriatic acid was also resorted to. At the end of sixteen months, counting from the first operation, the patient had fully recovered, and was dismissed.

Aquapuncture.—Dr. J. T. Whitaker describes (translation from *Gaz. des Hôpitaux*) under this name a new and ingenious mode of revulsion: To a small force-pump a leaden tube is adjusted whose extremity is filiform. A slight pressure on the lever of the pump suffices for the introduction of the capillary point, and a few grammes of water are injected under the skin. A small pale elevation of the integument ensues, with an occasional drop of blood in the centre. The first pain caused by the penetration of the water is severe enough, but this soon subsides, and in 15 or 20 minutes the effusion disappears. In a case where muscular pains in the sacro-lumbar mass were accompanied by a vesical atony of chronic duration and prostatic hypertrophy, twenty-eight points of aquapuncture in the region of the pain were followed by instantaneous relief, which still remained after 40 days. Eight points of aquapuncture, in a case of rachitic pains with prostatorrhœa, produced instant relief. Fifteen aquapunctures produced a complete cessation of the abdominal pains in a case of metritis with slight cystitis.—*Cincinnati Lancet and Observer.*

A Case of Coccydynia.—Dr. W. R. Fox (*Chicago Med. Examiner*) reports the case of a lady who complained of a very severe pain in the region of the coccyx. She had been delivered of her first child after a tedious labor, and her recovery was also tedious. The coccygeal pain was very much aggravated by sitting, walking, or rising from the sitting posture. Examination revealed the lower joint of the coccyx to be motionless and tender to the touch. Pelvic organs healthy, except slight prolapsus uteri. Advising amputation of the coccyx, she consented to the operation. The two lower bones were separated from their attachments and severed at their second joint by small bone forceps. The result was perfectly satisfactory.—*Chicago Medical Examiner.*

NEURALGIA OF THE OVARIES.—Dr. J. T. Newman reports three cases of this affection, in which the symptoms were similar. For some time they had had painful menstruation, considerable fulness in the iliac regions, with great tenderness, and severe pains shooting down the inner parts of the thighs. Upon the administration of muriate of ammonia and tr. of aconite the trouble disappeared in a few days.—*Chicago Medical Examiner.*

OIL OF TURPENTINE IN COMPLICATIONS OF PERTUSSIS.—According to Bedford Brown, of Alexandria, Va. (*Am. Jour. Medical Sciences*), no other drug exerts so prompt and universal an influence over the entire secernent system of membranes, as sudorific, diuretic, expectorant, and alterative, as the oil of turpentine. These peculiar powers render its action applicable to the treatment of the grave forms of hooping-cough and its dangerous complications, such as infantile remittent or gastric fever, a continued form of irritative fever, bronchitis, hæmoptysis, convulsions, dysentery, and enteritis.

EXCISION OF THE ENTIRE SCAPULA WITH PRESERVATION OF A USEFUL ARM.—M. Schuppert, M.D., New Orleans, La. (*The N. O. Jour. of Med.*), reports the successful removal of the right scapula from a German woman, 36 years old, on account of an *Osteochondroma*, which arrested the active and passive motions of the humerus. The tumor weighed six pounds, and measured respectively 0.35 and 0.40 metre in circumference. The sutures were removed on the third day. The wound was syringed out daily with glycerine containing 10 per cent. of carbolic acid. Seventy-two days after the operation the last secreting opening had closed.

At the present date—eighteen months after the operation—there is no indication of reappearance of the disease in any part of the body. The right arm has no artificial support, and is more useful than before the operation. There is sufficient strength in the extremity to lift a weight of thirty pounds and throw it a fair distance.

MUSCULAR LABOR OF THE UTERUS IN PARTURITION.—Prof. Haughton in his investigations upon this subject has shown with conclusiveness that the expulsive force of the uterus employed in dilating the os in the first stage of labor amounted to 3·4 lbs. on the square inch; and he compared this with the conclusion arrived at by Dr. Matthews Duncan, that the membranes required a force of 3.1 lbs. on the square inch for their rupture. He pointed out that the expulsive power of the uterus was just capable of rupturing the membranes and no more; and he illustrated by this comparison the beautiful and wonderful economy of nature evidenced in the human system. He found, however, that the expulsive force capable of being voluntarily exerted by the woman was enormously greater than that of the uterus, and was equivalent to 38.6 lbs. on the square inch, and he believed that it was by this force, in the greatest measure, that the expulsion of the fœtus was effected. Thus the involuntary and voluntary force amounted to 42 lbs. to the square inch, which, calculating the fœtal head to have a diameter of 4½ inches, would represent the enormous force of 593, or about a quarter of a ton, which might be engaged in parturition.—*Med. Press and Circular.*

DYSPHAGIA TREATED BY LARGE DOSES OF ATROPINE ADMINISTERED HYPODERMICALLY.—A woman who had some months before swallowed a quantity of sulphuric acid, had dysphagia, vomiting, and pain after swallowing food. There was cicatricial contraction of the œsophagus, but the symptoms of the obstruction varied in intensity. Dr. Murchison thought the use of atropine was indicated for the relief of the spasm; the patient was very much benefited by its use. The dose administered hypodermically, was at first 1-40th of a grain, once daily. It was afterwards increased to 1-30th, and then to 1-20 gr. occasionally, once daily; finally 1-14th gr. was given twice daily, although 1-7th gr. was at last given daily. No effect on the pupil was produced.—*Richmond and Louisville Medical Journal.*

DETECTION OF CHLOROFORM AFTER DEATH.—Dr. Thomas Stevenson (*Guy's Hospital Reports*) refers to a death from inhalation of chloroform, the patient being a powerful, muscular man, who was to have the tendo-Achillis cut for deformity. The solid and fluid parts of the body were subjected to analysis, in order to detect chloroform. The process of Duroc was employed, by which the chloroform is decomposed into chlorine, hydrochloric acid, and other products; and the two first named substances are absorbed by nitrate of silver. The result showed the presence of the agent.—*Pacific Medical and Surgical Journal.*

MEASLES IN A NEW-BORN CHILD.—Dr. Isaac Smith reports to the *American Jour. Med. Sciences*, the case of an infant born while the mother was about to break out with measles. Next day both mother and child were covered with the eruption.

THE DEVELOPMENT OF THE CEREBELLUM IN THE INSANE.—Dr. Meynart has recently reported that the brain of insane persons presents a remarkable development of the cerebellum, and that, on the other hand, its excess is much more considerable in women than in men, other circumstances being equal.—*Med. Press and Circular.*

INJECTIONS OF CHLORATE OF POTASH IN GONORRHŒA.—Pascual Cardila y Sanchez recommends (St. Louis *Med. and Surg. Journal*) injections of chlorate of potash (16 grs. to the ounce) in the second stage of gonorrhœa and in gleet. The injections should be frequently repeated, and continued several days after the discharge has ceased. They are less apt to fail in the second stage of gonorrhœa than in gleet.

SULPHUROUS ACID IN SYPHILITIC ULCERATION.—Dr. Murchison has recently tested this remedy, with a favorable result, in the case of an old woman with tertiary syphilitic ulceration of the pharynx, involving deeply the posterior pillars of the fauces. Iodide of potassium with chlorate of potash was employed internally, while sulphurous acid (one part to four of water) was used locally in the form of spray. The ulceration was speedily checked, and continued to improve so long as the application was kept up. When the treatment was discontinued for a short time the ulceration recommenced.

HYPODERMIC USE OF CARBOLIC ACID IN INTERMITTENT FEVER.—On the authority of Calvert & Co., of Manchester, it is stated that carbolic acid is a valuable remedy in intermittent fever in doses of two-thirds of a grain in twenty minims of water, administered hypodermically.—*Pacific Medical and Surgical Journal.*

THE CAUSE OF THE FIRST SOUND OF THE HEART.—E. Groux, M.D., of Brooklyn, N. Y., believes that the first sound of the heart is entirely due to muscular action, the second to the closure of the semi-lunar valves of the aorta and pulmonary artery. The movements of the auricles are synchronous. With regard to the vexed point of the nature of the pulsating tumor seen in the sternal fissure, on his own person, the Dr. believes it to be the right auricle, instead of the right ventricle, as laid down by Virchow.—*Cor. Med. and Surg. Reporter.*

PHYSIOLOGY OF THE BLOOD.—In a recent paper by M. Savotti, in the *Centralblatt*, he describes a phenomenon of great interest, and hitherto unobserved—the entrance of entire pigment-cells into the channels of the capillaries and smaller veins of the web of the frog's foot through their walls. This is the converse process to that exit of white corpuscles of the blood through the walls of the blood-vessels, which has attracted much attention, and as to which the researches have been brought under the notice of our readers. M. Savotti uses a dilute solution of sulphuric acid—2 per cent. The cells contract and become aggregated around the minute vessels. Then, putting forth processes, one pierces the wall of the vessel and enters its cavity. The whole cell sometimes is slowly drawn in, and after remaining adherent for a time to the wall of the vessel, gradually moves onward with the current of blood. The observation is one of great physiological and pathological interest. It will of course require verification.—*British Med. Journal.*

PUERPERAL FEVER.—Dr. Matthews Duncan says of this fever: Puerperal fever, or metria, is to me a hotbed of insufficient and false hypothesis. I do not believe there is any such single disease. The term includes a variety of diseases, and a variety of modifications or terminations of diseases. It is familiarly described as a zymotic disease. It is described universally as occurring in epidemics; not merely as an epidemic. I feel certain, and believe I can prove, that an epidemic of puerperal fever never occurred,—that no accepted definition of an epidemic can be made to include metria. When authors speak of epidemics of metria, of puerperal fever sweeping over a country, as they do speak, they are merely giving the reins to a misleading hypothesis which suits their present purposes or fancies. This disease is described as being contagious, or infectious, or both; but the authors who do this forget, with an almost ridiculous carelessness, to define what the disease is of which they are speaking so confidently, to show whether there is any such fever or not, and still more to define contagion and infection.—*Lancet.*

A MODIFICATION OF THE OPERATION FOR ARTIFICIAL PUPIL.—M. Liebreich has just presented to the *Académie des Sciences* an instrument which he has devised for the purpose of modifying the shape of the artificial pupil more surely, and more in accordance with the demands of each individual case than hitherto. It depends on the application of a mechanical principle, which has not as yet been utilized in surgery, and consists of a forceps whose handles do not open in the ordinary manner, but which revolve on a longitudinal axis in such a way that their rotation both opens and closes their curved extremities. Introduced into the anterior chamber by a narrow incision through the cornea, the forceps may be widely opened without the part of the instrument engaged in the wound sharing in the motion in the slightest degree. Consequently this forceps can be introduced in any given direction, whereas the instrument hitherto employed could not deviate from the radial direction.

IS DIABETES A NERVOUS DISEASE?—Dr. Dickinson, in his recent paper before the Royal Medical and Chirurgical Society, after showing the *post-mortem* appearance of the brain and spinal cord in four cases of diabetes, says it would seem that diabetes is associated with an organic change, which may be briefly described as a destruction of the nervous matter along the arteries of the brain and cord. He thinks we may give up the view that these changes are consequent upon the diabetic state of the blood, and grant that the nervous alterations *produce* the glycosuria. The alterations in the brain are, in nature and seat, those which physiology has shown are capable of producing diabetes. The urine often becomes saccharine in consequence of injuries of the head, apoplectic seizures, intra-cranial tumors, and cerebral irritation. Diabetes, though sometimes hereditary, continually results from circumstances exerting a depressing or otherwise injurious action on the nervous functions. Among these may be mentioned mental disturbance, rage, grief, anxiety and toil, dissipation, and especially sexual excesses.—*Medical Press and Circular.*

A NEW TEST FOR ALBUMEN.—Dr. Tidy, in addition to a mixture of equal volumes of glacial acetic and carbolic acid, recommends, as a very delicate test for albumen, the addition first of ten drops of alcohol at 0·805, and subsequently the addition of carbolic acid. This is, he maintains, a very delicate test for albumen, much more so than nitric acid and boiling. The tube must be shaken and allowed to stand a minute.

CARBOLIC ACID IN PSORIASIS.—Dr. M'Call Anderson prescribes carbolic acid in psoriasis in doses of from three to ten grains thrice daily, and says he has good results from this treatment. The following is the formula he employs: Crystallized carbolic acid, three drachms; glycerine, one ounce; water to six ounces; a teaspoonful in a large wine-glassful of water thrice daily before meals.

BROMIDE OF POTASSIUM.—A paper by M. Namias, of Venice, was lately read before the *Académie des Sciences* on the subject of the action of this salt. From researches carried on for some time, the author concludes that the bromide is a medicine which accumulates in the economy, and soon saturates the organism as a consequence of its non-excretion through the urinary tract.

In remarking on this communication, M. Balard, who first discovered bromium, took occasion to express his regret that the bromide of sodium had not been tried in therapeutics in preference to the bromide of potassium. To introduce into the system the salts of potash is by no means a matter of indifference, whereas the perfect tolerance of the salts of soda by the human body is well known.

MANGANESE IN BLOOD AND MILK.—A memoir just read at the Royal Academy of Sciences of Italy, by Professor Polucci, announces a great discovery. It is the constant presence of manganese in the human blood. In more than twenty analyses of the blood of persons of different sexes, professions, health, and temperament, there was always found a certain proportion of manganese.

One of the consequences of this fact is, that the metal ought to be also found in milk. Submitted to experiment, this deduction is entirely confirmed. In thirty-four analyses of milk, twenty-three of which were human, four from the cow, and four from the goat, the presence of manganese was constantly observed.—*Medical Press and Circular.*

HEREDITARY SYPHILIS.—Mr. Henry Lee accounts for the transmission of syphilis to the ovum, and thence to the mother, years after the secondary stage has passed in the father, by saying that the internal structures may yield a diseased secretion capable of imparting syphilis long after the skin has ceased to be liable to do so.—*Med. Press & Circular.*

DIURETICS.—Dr. Nunneley, of York, in experimenting on himself with citrate of potash, in doses of 10

to 18 drachms in twenty-four hours, found his urine increased 2½ ounces, whilst the urea decreased 84 grains, and the solids 60 grains. The spiritus etheris nitrici, in doses of 10 to 18 drachms in twenty-four hours, slightly increased the water, and diminished the urea and solids; and the oil of juniper, in doses of 30 or 40 drops in twenty-four hours, slightly increased the urea and solids. It would appear from these facts that the substances are by no means very powerful diuretics.—*Med. Press & Circular.*

The Progress of Surgery.—Mr. Bryant, in an oration in the Hunterian Society, relates how, in 1820, bleeding, calomel, and opium were employed in strangulated hernia; how gonorrhœa was treated by bleeding and mercury. In 1835 Dr. Babington related how a lady had been bled every week to 10 or 12 ounces. A seton used in 1830 to be passed down to the urethra in tetanus; and Dr. Hamilton used to recommend the patients with ovarian dropsy to beat the belly with a steel instrument with four brass balls at the end. Eggs were used as pessaries, too. All this within this wonderful century!—*Med. Press & Circular.*

Recurrent Hemorrhage.—Mr. Paget, after mentioning that recurrent hemorrhage is essentially due to reaction, and comes on more rapidly in strong persons after amputation than in the weak, deprecates the plan of giving much stimulation to patients after operation, as likely to be followed by bleeding. In cases of morbid or cancerous growths recurrent hemorrhage is peculiarly apt to occur, or after some inflammation or acute pain in the part. In such cases it is advisable after amputation to sling the limb, and leave the vessels exposed to the air. If not sufficient, ice should be applied, and in desperate cases compression of the main artery by tourniquet, or opening up of the flaps and tying the vessels again. The main vessel should not be bled until it is ascertained whether, if that were done, bleeding would be likely to cease or not.—*Med. Press & Circular.*

Uterine Cancer.—Dr. Routh speaks hopefully of some cases of cancer of the womb. Cancer is not always a blood disease, although doubtless often so. Even if it were, topical remedies are useful in syphilis. Why not in this? The progress of uterine cancer is not very rapid. Iodine, carbolic acid, and bromine seem especially indicated as escharotics in uterine cancer; or, when the mass is large, the red-hot iron is useful. In the case of one patient treated by bromine caustic, the patient eight months afterwards was still quite well. He thinks that in all epithelioma, where the uterus is still movable, the cancer may be cured. If the growth is large he usually destroys it by red-hot iron, or by the écraseur of Dr. Hicks. He prefers bromine as a caustic, dissolved in spirit, moulding a cup of gutta-percha to the diseased uterus; lining this with cotton wadding, and applying this, saturated with a solution of bromine, directly to the part, keeping this in its place by means of cotton soaked in carbonate of soda for 24 hours. The solution used of bromine was 1 to 5. It should be made a few minutes before it is used. Great care must be taken lest explosion takes place, and the bromine is added slowly to the spirit. Fowler's solution is taken at meals.—*Med. Press & Circular.*

Shot a Remedy for Ileus.—Dr. Maydieu, of Argent, in France, states in the *Journ. de Méd. Prat.* quoted by the *Bulletin de Thérap.*, May 15, 1870, that for seventeen years he had treated cases of ileus by the means recommended in books, and had always failed. Four years ago he tried the old remedy of heavy substances ingested into the intestinal canal, and has been invariably successful *in the twelve cases* which have latterly come under his care. Instead of actual bullets or crude mercury, M. Maydieu uses shot No. 5. About seven ounces are carefully and repeatedly washed, then mixed with four ounces of olive oil, and the patient takes a dessert-spoonful of the combination every half-hour. Five or six hours afterwards the vomiting ceases, gases are expelled, and an alvine evacuation is obtained. The author does not, however, neglect other means, such as warm baths, soothing applications, &c., and especially insists upon enemata with milk and honey—viz., one pint of the former to three tablespoonfuls of the latter.—*Lancet.*

Safe Anæsthetics.—M. Sauer, a surgeon-dentist of Berlin, after having performed various comparative experiments with anæsthetic substances, has come to the conclusion that the very best is a mixture of protoxide of nitrogen, chloroform, and atmospheric air. He considers this compound to be free from the dangers attendant on the use of either chloroform or the protoxide alone. The proportions which he advocates and employs are the following:—Liquid chloroform, six grammes; atmospheric air, three-quarters of a litre; and protoxide of nitrogen, sixteen litres.

The Properties of Ipecacuanha.—Dr. F. J. Brown, of London (*British Med. Journal*), at a meeting of the South-Eastern Branch Association, London, advocated Mr. Higginbothan's mode of treatment of uterine hemorrhage by emetic doses of ipecacuanha—30 grains. *Post-partum* hemorrhage is arrested within three minutes. He also stated that hip-joint disease is readily cured by this agent, in three-grain doses three times a day.

External Use of Iodine.—Dr. Brown, of London (*British Medical Journal*), recommends a formula for the external use of iodine, by which the color is bleached whilst the effects are augmented, viz.: equal parts of tincture of iodine and of liquor sodæ chloratæ.

Large Calculus.—Dr. Watson (*British Med. Journal*) exhibited to the members of the Medico-Chirurgical Society of Edinburgh, April 6th, an uric acid calculus, which he removed from a boy aged 17; it weighed eight and a quarter ounces, and measured 9 inches in its long circumference. The patient died on the fourth day, and it was found that the bladder showed traces of epithelial disease.

Osteo-Sarcoma.—Dr. Hammer, of St. Louis, Mo. (*Med. Archives*), exhibited before the *St. Louis Medical Society* a patient upon whom he had successfully resected the superior maxillary bone, on account of an osteo-sarcoma about the size of a pigeon's egg.

Anointing in Infantile Disorders.—H. Guard Knaggs, M.D., F.L.S. (*Lond. Lancet*) during the past 11 months, has been testing, with uniformly successful results, the value of a very simple method of treating such infantile complaints as atrophy, bronchitis, convulsions, diarrhœa, febrile disturbance generally, and indeed all disorders of childhood which are accompanied by an unnatural state of the skin. The treatment simply consists in smearing with salad oil the whole surface of the body, from the crown of the head to the tips of the fingers and toes, the process being repeated every 12, 6, or even 4 hours, according to the urgency of the case. Of course the use of a long flannel gown or small blanket is obvious, and the fluid should be slightly warmed.

It seems as though the good old German and Roman practice will have to come up again.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

SHALL WE CONSULT WITH FEMALE PHYSICIANS?

AT the recent meeting of the Pennsylvania State Medical Society, held at Philadelphia, the question of woman's rights in medicine came up, and received a very full discussion. Our Philadelphian brethren have made themselves experts in the matter in question, and their opinions *pro* and *con* should be respected accordingly by the profession at large. We regret our inability to publish the proceedings of the Society in question *in extenso;* but, in lieu of it, we will endeavor to give an idea of the case from the last standpoint. In order to do this we shall glance at the respective doings of the Philadelphia County Society and the Pennsylvania State Medical Society, in reference to the point at issue, from the time the general question was first presented to them for consideration.

At the meeting of the Pennsylvania State Medical Society in 1860, at the instance of the Philadelphia County Medical Society, a resolution was adopted to the effect that it was unprofessional for members to consult with the graduates or *attachés* of the Woman's Medical College of Philadelphia. These objections were based upon the fact that the institution was not regularly organized, and not conducted in a manner to insure the reception of a good medical education by the students. At a meeting of the State Society, held in 1866, after some discussion this resolution was reconsidered, and referred back to the County Society for a report. A committee was accordingly appointed, with Dr. D. Francis Condie as chairman, and the said committee, at a conversational meeting of the latter body, held March 13, 1867, duly presented a protest against the repeal of the resolution, and the following was adopted accordingly:—

"*Resolved*, That the Philadelphia County Medical Society cannot consent to the repeal of the resolution passed by the Medical Society of the State of Pennsylvania, at its session of 1860, in reference 'to the graduates of Female Medical Colleges, *as at present constituted;*' and they hereby instruct the delegates from the Society to the next session of the State Society, to use all honorable means to prevent the repeal of the said resolution, which they believe to be as loudly called for now as at the period when it was passed.

"All of which is most respectfully submitted by

"D. FRANCIS CONDIE,
"JOHN F. LAMB,
"A majority of the committee.

"PHILADELPHIA, March 13, 1867."

This was followed, after a heated discussion, by the passage of another to this effect:—

"Nevertheless, nothing in the foregoing resolution shall be construed to forbid any member of this Society from consulting with any female practitioner who shall be declared by the American Medical Association as regularly educated, and who gives sufficient evidence of strict adherence on her part to the code of medical ethics."

Within a week after the passage of the above the subject was again brought up, and an attempt made to prove that the college was to all intents and purposes a regular one. But it was shown that one of the professors had issued a circular calling the attention of the people to some infallible cholera remedies which he had for sale, and the result was as might have been imagined. At the same meeting much was said as to the physical and moral propriety of women studying medicine, and the following explicit declaration was made:—

"*Resolved*, That in conformity with what we believe to be due to the profession, the community in general, and the female portion of it in particular, we cannot offer any encouragement to women becoming practitioners of medicine, nor can we consent, on these grounds, to meet in consultation such practitioners."

Nothing more was accomplished until the fall of 1868, when the following was passed:—

"*Resolved*, That it is the sense of this Society that the preambles and resolutions adopted by it in regard to Female Colleges, their professors and graduates, are such as do disqualify such professors and graduates from becoming members of this Society; and further, that the accepting and filling of any professional chair in a Female College by a member of this Society disqualifies him for active continued membership of this body; and furthermore, that the essence and sense of the preamble and resolutions referred to deny to the members of this Society the right to professionally consult with any professor or graduate of a Female College."

Since the passage of that resolution several of the members openly attached themselves to the college, and did at the same time refuse to withdraw from the Society, notwithstanding their attention had been drawn to the propriety of so doing by a special vote of the body.

It was principally concerning the right to enforce this resolution of the County Society that the recent discussion before the State Society was held. It is

claimed that the Woman's Medical College is in every respect regular, and on that ground should be recognized in representation and consultation; and if such be the case we see no reason why the obnoxious resolution cannot be rescinded. With a conviction that women can distinguish themselves better in any other sphere than that of medicine, we are nevertheless in favor of having them try to do what they can in their newly-chosen calling. In order that this may be fairly done, we must not interfere with their efforts to elevate their requirements for graduation, but rather aid them in so doing—that the excuse may not afterwards be offered that fair opportunities for improvement were not granted them. The discussion in Philadelphia has shown that the passage of the resolution in question, although right enough in the beginning, was wrong in the end, as proven by the facts presented, and the indisposition to expel those offending members who still maintain their connection with the college. As the whole matter lies over for action at the next meeting of the American Medical Association, and as the President is believed to be a strong advocate for the college, there will no doubt be a strong effort to settle the status of the institution for ever and establish its right to honorable recognition. Thus far nothing is positively established as to whether we can or cannot consult with regular female physicians, and until the question is settled every one must do as he pleases, trusting to a fair trial to prove that ladies are, on physical and moral grounds, unfitted for such a relationship. We are willing to give the lady every opportunity to do what she thinks she can for good in medicine, because we are confident that it is the surest and best way to prove her absolute unfitness for the task. If she is a regular physician let us consult with her, and if possible "throw aside the question of sex for the sake of pure science."

Reviews and Notices of Books.

OBSTETRIC OPERATIONS, including the Treatment of Hemorrhage. By ROBERT BARNES, M.D. Lond., F.R.C.P., Obstetric Physician to, and Lecturer on Midwifery and the Diseases of Women and Children at, St. Thomas's Hospital; Examiner in Midwifery to the Royal College of Physicians, and to the Royal College of Surgeons; formerly Obstetric Physician to the London Hospital, and late Physician to the Eastern Division of the Royal Maternity Charity. With Additions by B. F. DAWSON, M.D. New York: D. Appleton & Co., 1870.

DR. BARNES'S valuable contribution to obstetric science is remarkable alike for the completeness with which all the necessary operations of midwifery are described, and for the humane conservatism insisted upon throughout in regard to their adoption. In his opening chapter the author expresses the opinion that "huge heaps of instruments may, without loss to science, and with great comfort to womankind, be cast into the furnace, and the ideas of their inventors melted out of them." On the other hand, he says in one of the chapters on forceps, "the absurd dread of possessing powerful instruments has long been the bugbear of English midwifery. It has been sought to make an instrument safe by making it weak. There can be no greater fallacy." All the various instruments are described in detail, together with their mode of operation, and the circumstances calling for their employment. The mechanism of labor, and the management of cases where nature is at fault, are treated of in a most satisfactory and masterly manner. The author boldly takes ground in favor of turning as a means of delivery in labor obstructed by pelvic deformity, regarding the performance as one holding out some hope for the child, and adding nothing to the danger or difficulty of perforation afterwards, if it should be necessary.

The chapters on "Sacrificial Midwifery" are entered on with evident reluctance; but the "border-land" once passed, the clear judgment of the author is conspicuous on every page, while all the opinions advanced are fortified by his large and varied experience. Some decided views are expressed regarding the induction of premature labor. Experience, the author thinks, "is adverse to the opinion that pregnancy exerts any beneficial influence upon phthisis." He believes, however, that pregnancy is less trying to a phthisical patient than labor and childbed, and that it is therefore desirable, in the interest of the mother, to postpone labor as long as possible. The author advises that premature labor should never, under any circumstances, be undertaken without the knowledge or sanction of some professional brother. In treating of habitual abortion he condemns the common neglect of curative and prophylactic measures. "Do not sit down disarmed and passive," he says, "under the influence of that ignorant dogma which asserts that women have a habit of aborting, that they are laboring under an abortive diathesis. This is no more than saying that women abort because they abort, which is not very instructive." Of the sequelæ of abortion, he says: "It must be remembered that a patient who has suffered abortion is liable to all the puerperal affections that assail women who have been delivered at term; for example, hemorrhage, phlegmasia dolens, septicæmia, and other forms of puerperal fever, and pelvic peritonitis."

The subject of hemorrhage in all its varieties occupies considerable space, and the method of using the perchloride of iron by injection, original with the author, is fully set forth. The closing chapter is devoted to twins and monsters, and the peculiar dangers attending their delivery. The work is one indispensable to the obstetrician, and of great value to every practitioner aud student.

The profession should be aware that this volume is not strictly a reprint of the English edition, but is made up of the lectures of Dr. Barnes as published in an English medical journal. These lectures have been collected and edited without the permission of the author. The English edition has had the advantage of correction and revision by Dr. Barnes, in lieu of which the American edition has been edited by a gentleman whose claims to distinction, as displayed on the title-page, are at least as numerous as those of the author himself. The additions made by the editor consist of three or four pages of remarks, interspersed throughout the book, and about fifteen pages of extracts from American authors. The dedication by the editor of a book not his own to a distinguished professor, is an anomaly in medical literature, and seems to us a very singular way of expressing "high regard and gratitude." The truth is that this sort of editing is merely a cheap and generally harmless means of achieving

publicity at the expense of others. But where it may deprive a book of the finishing touches of the author it becomes intrusive and objectionable.

THE MEDICAL REGISTER of New York and vicinity for the year commencing June 1, 1870, published under the supervision of the New York Medico-Historical Society. E. Lee Jones, M.D., Editor. Vol. VIII. New York: Bradstreet Press. 16mo., pp. 410.

WE have said so much concerning the advantages of medical registration, and have remarked so frequently upon the enterprise of the Medico-Historical Society in proving the desirability of a conscientious trial of the system, that to do anything more upon the subject would seem like a work of supererogation. But we cannot resist the temptation of saying another word in favor of the Association on the occasion of the appearance of its last volume. The work before us, which appears earlier than usual, is everything that its patrons can expect in completeness and thoroughness of detail. The editor, Dr. E. Lee Jones, has shown himself eminently fitted for the work, and deserves great credit for the fidelity with which he has discharged the trusts of the Association. The recent action of the State Medical Society has been fruitful in furnishing a more or less complete list of the members of the county societies throughout the State, and as the respective secretaries get accustomed to make their returns promptly and regularly, we see no reason why the name of every regular practitioner in the State may not be found in its proper place. In the present volume many new institutions are noticed and much very desirable information added. As a whole, we believe that the work has not its equal for reliability and completeness in any language. We cordially recommend it to every medical man throughout the country, who is desirous of being well informed concerning everything and everybody of any medical interest in New York or its immediate vicinity. The book is very well printed.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, MAY 2, 1870.

DR. GEO. T. ELLIOT, PRESIDENT, in the Chair.

THE report of the Committee on Intelligence was read by Dr. Thompson, and that of the Committee on Diseases by Dr. Raborg.

ORIGIN OF DIABETES.

DR. WM. T. LUSK read an important paper *On the Origin of Diabetes, with some New Experiments regarding the Glycogenic Function of the Liver.* He carefully reviewed the history of the doctrine of sugar-formation by the liver, with special reference to the experiments of Bernard, who first announced it, of Pavy, perhaps his ablest opponent, and of Flint, Jr., who, a year or more since, endeavored to reconcile their conflicting observations. He then narrated his own experiments, undertaken to test the validity of Pavy's objection, that the sugar discovered by Bernard in the liver and the blood of the hepatic veins was the result not of a physiological, but of a post-mortem process. For the details of these interesting experiments we refer the reader to the paper itself, in the *New York Medical Journal* for July, and present here simply the conclusions derived from them:

"1. That the blood of the general system, in carnivorous animals confined to a nitrogenous diet, contains appreciable quantities of glucose, not only during the period of digestion, as admitted by Bernard, but even in cases where animals have been deprived of food for a considerable period of time.

"2. That the blood of the right side of the heart contains from one-fourth to one-half of a grain of glucose per fluidounce, under strictly physiological conditions.

"3. That the quantity of glucose in the right side of the heart is from two to four times greater than that found, under corresponding circumstances, in the jugular vein.

"4. That this excess argues a by no means insignificant amount of sugar in the pure hepatic blood, before it has become largely diluted with the comparatively non-saccharine fluids of the venæ cavæ.

"5. That we are forced to admit the fact of sugar-formation by the liver, though we fail to detect the presence of sugar in the liver-tissue when, after death, the fermentation of the glycogenic matter is prevented."

"Now are we, in view of all the facts, justified in further assuming that the liver is the sole source of the sugar found in the economy? The question is of the utmost practical importance, as involving the origin of diabetes." Again our limits compel us to omit the writer's discussion of this question, and to give only an extract from his summary: "The causes of diabetes are various, and the source probably not confined to a single organ. At the same time the liver is to be regarded as the most active agent in sugar-formation. At times it may be the indirect cause of diabetes, by its failure to fulfil its function of arresting the passage of saccharine principles through it. We are to regard the labors of Bernard, Pavy, and Bouchardat as severally adding to the sum of our knowledge of diabetes. There is no reason to suppose that the truth lies in any individual exclusive theory."

DR. AUSTIN FLINT, SR. — To make a beginning of the discussion, I offer a single observation. It sometimes happens that pathology communicates facts of importance in their bearing upon physiology, and it seems to me that in this instance we have an illustration of it. That in diabetes a change of diet, so as to eliminate in great measure the starchy and saccharine principles, has a very marked effect in diminishing the amount of sugar in the urine, is well known; though perhaps all may not have noticed the great extent to which the sugar is diminished. This fact seems to point to the view that the formation of sugar depends in no small degree upon the diet.

I have two cases of diabetes now under my care. In the first, which I have had under observation for a considerable time, the treatment has consisted alone in the regulation of diet. On this treatment the urine has been reduced to its normal amount, and its specific gravity has fallen from 1040 to below 1030. Reagents still show the presence of sugar; but, were it not for this, the patient would consider himself perfectly well —indeed, he feels better than before he discovered his disease. The second case has been under observation but a short time, yet even in that time the urine has been reduced in amount one-half, and in specific gravity from 1040 to 1030.

The dietetic treatment can be made very comfortable to the patient, if only the physician will take sufficient pains to explain the range of articles allowed, and the patient sufficient pains to prepare them. With proper variety and proper cooking the diet is not unpleasant, notwithstanding the total exclusion of saccharine articles and the almost complete exclusion of amylaceous.

Dr. Gouverneur M. Smith remarked that he had recently gathered some facts in relation to the pathology of diabetes, but was not as yet prepared to present them, as he was still investigating the subject, and anticipated making future use of the facts elicited.

In a communication received in February last from Dr. Dickinson, of London, the Doctor had informed him that, from observation of five diabetic patients, it seemed to him there are constant and very peculiar changes in the cerebro-spinal system, resembling in some respects those found in the general paralysis of the insane, and this led him to the inference that diabetes is primarily a nervous disease. An abstract of Dr. Dickinson's views is to be found in the *Lancet* of February 19, 1870.

Dr. Smith would on this occasion only allude to two cases. One of them he had to-day seen—a man of active business habits, nervous, dyspeptic, addicted to excessive venery. He was so fond of sugar as constantly to carry bonbons about with him. It was a peculiarity in the case that the diuresis was not excessive. The patient had been, for about two weeks, on a treatment chiefly dietetic, and the glycosuria had diminished, as in the case just alluded to by Dr. Flint. The other case had been under his care within a year, and had terminated in a peculiar manner. The patient was a gentleman of means, who had been conspicuous for his mental activity and commercial enterprise. He had suffered with diabetes for several years. Leaving business, he travelled in Europe, and, while free from care and using the alkaline waters of the German Spas, he was relieved from the more distressing symptoms of his malady. He returned to this country intending to make but a brief stay. His urine examined about this time still showed the presence of sugar. While preparing to retire one evening he pricked the bulb of the great toe with a tooth of a tortoise-shell pocket-comb, which had broken off and fallen on the floor. This puncture excited a peculiar morbid condition, ending in mortification of the toe and finally of nearly the entire foot. The gangrene partook of the senile character, and its progress was not rapid, the accident occurring April 5, 1869, and the patient dying from exhaustion on the 19th of the following July. Dr. Thomas M. Markoe early saw this case in consultation, and at a later period also Dr. Alfred C. Post. Gangrene of the lower extremities was occasionally a termination of diabetes, irrespective of any traumatic cause, Marsh, Colles, Marchal, and others reporting cases of this nature. No such termination, however, had ever been observed by the attendants in the case alluded to. As boils, carbuncles, and gangrene were liable to occur during the course of diabetes, so, conversely, during the outbreak of boils and carbuncles there occasionally appeared a transient diabetes, such instances having been noted by Prout, Wagner, Vulpian, and others. This latter clinical fact was of interest in connection with the subject of glycogenesis.

Dr. J. C. Peters referred to a case of diabetes which had, in two attacks, been preceded by jaundice, indicating some connection of the disease with the liver. A case under his care last summer had surprisingly improved upon change of diet and tincture of nux vomica, five drops thrice a day.

Dr. Peaslee.—This is a subject upon which, for twenty years past, I have thought more, perhaps, than upon any other in the whole domain of pathology; but I have come to no satisfactory conclusion. There are one or two points, however, which may aid us in coming to such a conclusion.

In the first place, while diabetes is so common in England and in this country, it is very uncommon in Germany. Some of our distinguished German *confrères* have told me that they had seen but two or three cases there in their lives. This would show that there are predisposing causes of great importance, coming probably under the class of dietetic or hygienic influences.

I think we may conclude, also, that the cause of this disease is not always to be found in the same organ—that it must not be made to depend entirely upon a certain condition of the liver. Its pathology is probably not simple, by any means. Doubtless there is more than one condition which may aid to produce it—more than one condition of the same organ, perhaps; or certain conditions which may affect different organs; or it may be the same condition of the different organs.

There is one point I think very probable—that the sugar is at any rate the result of disassimilation. The fact that in the progress of the disease there is such rapid emaciation goes to show that the disease essentially consists in a development of sugar in consequence of disassimilation of tissue. Now whether it be from disassimilation of the liver alone that we are having sugar formed all the while during our lives—whether from that alone, or from disassimilation of other parts also—remains to be seen. The sugar of milk is doubtless produced from disassimilation of the substance of the mammary gland itself, not by a definite act of secretion. And no more is the production of sugar in the liver the result of a special secretion of the organ; it is a part of the normal process of nutrition.

It is a very interesting fact that the sugar of diabetes is grape sugar, glucose, hepatic sugar—words all indicating a sugar identical in composition, though from different sources. Interesting, too, as showing that the affection has not one cause, but many, is the fact that the tincture of nux vomica, which we have all made use of in diabetes,—for all of us who have been some years in practice have seen many cases of the disease,—is in some cases valuable, in others not at all; and so with the tincture of chloride of iron, and with the alkalies. The fact that diabetes often follows icterus, as stated by Dr. Peters, and that it is necessary to modify the secretion of the liver,—that is, to modify its nutrition,—points in the same direction. The disease is due to several causes, and it will be for us to decide what is its pathology in each instance, and address our remedies to the organ affected. When we have left the narrow view that confines the origin of diabetes to one organ alone, we have taken the first step toward the true knowledge of its pathology.

Dr. Austin Flint, Jr.—I have naturally taken a great deal of interest in this paper, not only from the importance of the physiological question involved, but also because it is a question in the investigation of which I have myself been very largely engaged. I would like to call the attention of the Society to one or two points in the paper of very great importance, which probably the modesty of Dr. Lusk prevented him from putting forward as prominently as they deserve, for they are his own property.

The point of greatest interest is the process which he has fixed upon for the quantitative determination of sugar in the blood. The Fehling test is a very valuable one for the determination of sugar in the urine, where it is not masked by other principles, and where the use of the test is attended with no difficulty; but when this same test is applied to determining the quantity of sugar in the blood, it is impossible, by the ordinary method, to make an accurate quantitative estimate, for the reasons that the proportion of sugar is usually very minute, and that the process of extraction in a clear so-

lution is somewhat complex. But by adopting Dr. Lusk's method of taking a number of test-tubes, each containing the same quantity of the test-liquid, and adding to each measured quantities of the clear extracts containing sugar, it is easy to see which of the test-liquids are the most completely decolorized, and present the greatest amount of precipitate, and in this way to arrive at a comparative estimate of the proportion of sugar. This method, applied to two liquids, cannot fail to give, in the most satisfactory manner, a definite idea of the relative proportion of sugar in each. I could only wish that Dr. Lusk had carried his process a little further, and separated and weighed the precipitate of copper. But perhaps this is not necessary in the present instance, in which the important point to determine is the preponderance of sugar in one or the other of the specimens examined.

I may perhaps be permitted to say a few words on my own experiments upon the glycogenic function of the liver. When I first began to teach physiology to medical classes, I found no difficulty in repeating the experiment of Bernard, and showing want of sugar in the portal blood, sugar in the substance of the liver, sugar in the hepatic blood, and in the right side of the heart. As, however, I gained in experience and experimental dexterity, I went through with the manipulations more rapidly; but the better I did it the more unsatisfactory was the result, slight traces of sugar only appearing in the extract from the substance of the liver. The explanation occurred to me—and I believe the idea is original with myself—that during life the liver is constantly producing sugar, but that the blood is as constantly washing it out. This explanation was suggested by the experiment of washing the liver free from sugar, by a current of water passed through the vessels; letting it stand awhile; and then finding sugar which had formed again in its substance.

Surveying the field to get the point of departure for further research, the view of Pavy and that of Bernard seemed to be the only two entitled to consideration. Bernard seemed to lack strength in the fact that, while Pavy said positively that there was no sugar in the liver during life, he never took the liver under the conditions prescribed by Pavy, and established the fact of the presence or absence of sugar; and Pavy was weak in this, that while Bernard said the blood of the hepatic vein invariably contained sugar, and the portal blood none, Pavy never applied the accurate quantitative test to the blood taken from these different vessels. Had he applied the test used by Dr. Lusk, he could not have failed to admit the preponderance of sugar in the blood of the hepatic veins. Pavy seemed unphilosophical, also, in assuming without reserve that the sugar in the blood was inevitably the consequence of post-mortem change, and allowing this idea to influence all his deductions. In some of his experiments he adopted the very rough process of injecting a solution of potash into the portal blood, which he said would arrest the production of sugar—an experiment in which the conditions were manifestly unphysiological.

It seemed to me a simple enough question to find out the truth of the matter. If the liver be constantly producing sugar during life, we ought certainly to be able to detect it. I set about my experiments in what seemed to me to be a simple, common-sense way. I had a dog for a long while in my possession, so that he was accustomed to me, and could be handled freely. This animal was fed exclusively upon meat. In making the experiment I placed him gently upon the operating table, keeping him perfectly tranquil; had him held on his back by assistants; and without the use of an anæsthetic, while the animal was perfectly quiet, I opened the abdomen in the whole length of the linea alba by a single sweep of the knife. I then cut off a piece of the liver, rinsed it from blood in a vessel of cold water, and cut it up into boiling water. The time between the first incision and cutting up the liver into boiling water was ten seconds. To all intents and purposes this was a living liver; and it is well known that boiling water prevents any post-mortem change of glycogenic matter into sugar. I never found a particle of sugar in an extract of the liver thus treated; and so Pavy seemed certainly right on this point.

The next question was to confirm the observations of Bernard upon the blood. I made several experiments upon this point in the following manner: I had the animal, a dog, held on his back, and kept perfectly tranquil. I first broke up the medulla oblongata; then applied a ligature to the portal vein as it enters the liver; then opened the abdomen and chest freely, cut out a portion of the liver, and cut it up into boiling water; I then applied a ligature above the renal veins in the abdomen, and a ligature above the hepatic veins in the chest, and collected the blood from the portal veins, and the blood coming from the liver. The entire operation, in an experiment which I have published in my work on physiology, only occupied sixty seconds. I found no sugar in the portal vein, and I found sugar in the hepatic vein. The experiment I allude to was performed before the class of the Bellevue Hospital Medical College, and in the presence of Dr. Lusk.

This experiment, which I have verified time and again, entirely confirms the experiments of Bernard and others, and I consider the question settled, that sugar is not contained in the blood of the portal vein, in animals confined to nitrogenized food, but is always contained in the blood of the hepatic veins. It seems to me that I have settled the question, also, that sugar is not contained in the substance of the liver during life; but that it is, none the less, formed in the liver during life, being washed out by the current of blood as it passes through, appearing, of course, in the blood of the hepatic veins. These facts harmonize the apparently discordant observations of Bernard and of Pavy, and give the first accurate notion of the exact mechanism of glycogenesis which is in accordance with all the well-established experimental facts.

With regard to the position taken by Dr. Peaslee, I can see no reason for regarding sugar as a product of disassimilation, and I can see every reason for considering it an alimentary substance. In my experiments upon cholesterine, I assumed that it was necessary to ascertain that this principle is actually discharged from the body, in order to prove it to be an excrementitious substance, or a product of disassimilation. If sugar be a product of disassimilation, it is a waste product. All such products are gotten rid of, cast off from the body. Sugar is never discharged from the body in health; sugar is taken as food; sugar is formed in the body. No one would call fat a product of disassimilation; and fat is taken as food, fat is formed in the body, as is sugar, and in its relations to nutrition presents many analogies with sugar. Fat is never discharged from the body in health.

There is one exception to this rule as regards the discharge of sugar and fat, and that is in the milk; and here we have a most curious departure from the general laws affecting the mechanism of secretion. It is a recognized fact that glandular epithelium is necessary for secretion; the remarkable exception is in the

mammary glands. These glands, rudimentary at birth, and in the male rudimentary throughout life, undergo one change in their development at puberty, but then are incapable of producing milk; they undergo another change during uterine gestation; and it is only in the latter part of this that they can secrete milk. When the secretion of milk is fully established, there are no secreting cells lining the glandular acini; and the bare membrane seems to be the agent which forms the butter, casein, and sugar. This, far from showing sugar to be an excrementitious substance, shows it to be a principle very necessary for the nourishment of the infant.

The observations which I made in 1868-69; their repetition soon after by Dieffenbach, who did not know of my own experiments; and the additional confirmation they have just received at the hands of Dr. Lusk, I think settle the question concerning the sugar-forming function of the liver.

DR. PEASLEE.—If Dr. Flint considers cholesterine a product of disassimilation, because it leaves the body after its conversion into another product, might we not also regard sugar as such a product if we can find substances leaving the body into which the sugar is convertible?

DR. FLINT, JR., replied to the question about cholesterine by giving his arguments to *prove* the change of cholesterine into stercorine. Dr. Peaslee would be perfectly right if he could prove that the sugar was converted into any other substance which was discharged from the body. But Dr. F. knew of no such substance into which sugar was convertible except carbonic acid, which, it was true, was diminished in diabetes. He also agreed with Dr. Peaslee, that we do not know what sugar does in the economy. We do not know that it forms any tissue. He regarded it as entirely analogous to fat, which is introduced into the body, consumed in the body, never discharged in health. They performed some function in nutrition, but what, he had not the slightest idea, and he thought the physiologists of the present day had not.

DR. CHANSEY asked what became of the sugar when taken as food in excessive amount. He had a patient who used to take some five or six pounds of sugar a day—thought he could not live without it. But no sugar could be detected in the urine; there was no diabetes. Some two or three years after the Doctor knew him, this man met with an injury to his leg. The limb mortified, and he died. Dr. C. had attributed the mortification to the great amount of sugar he ate. Lately he had had a child as a patient, that he found breaking out with little sores, which mortified; and he discovered that the child was always eating candy.

DR. FLINT, JR.—If I do not know what becomes of the sugar taken normally as food, I am very sure I do not know what becomes of the excess in the abnormal condition where it is craved. I judge that, in such cases, it is often disposed of in the same way that the ordinary amount is disposed of. It is certain, however, that diabetes has been produced in animals by feeding them with sugar.

THE HARVEY STATUE.

Miscellaneous business being in order, the Special Committee appointed at the meeting of the 21st of February, to inquire into the expediency of recommending that a bronze copy of Horatio Stone's statue of Harvey be placed in Central Park, reported in favor of the proposition; and the Committee was, by vote of the Society, empowered to appeal to the public for funds to consummate it.

The Society adjourned.

REPORT OF THE COMMITTEE ON INTELLIGENCE, READ AT A STATED MEETING, JUNE 6TH, 1870.

By BRADFORD S. THOMPSON, M.D.,

SECRETARY OF COMMITTEE.

MR. PRESIDENT—The subjoined original items are respectfully submitted:—

Dr. Alfred Underhill, of New York, your chairman, reports the following case of *infantile diarrhœa*, occurring in his practice:—A fine male infant of six months, taken from the breast in consequence of tuberculosis in the mother, and living on milk from a healthy cow, was attacked with diarrhœa. When first seen, May 10th, 1870, the diarrhœa had existed a fortnight; the child was much emaciated, its abdomen was flat and flabby, flesh soft, and extremities below the natural temperature. Its head was hot, eyes sunken, and when awake it uttered a constant, fretful cry; its sleep consisted of short naps, from which it suddenly started; occasional vomiting of food; pulse weak, 120 in a minute; the stools frequent, from 20 to 24 in twenty-four hours, of a greenish, offensive character, and a portion resembling half-digested milk.

With reference to the treatment, the mother was first directed to administer the food at regular intervals, and in suitable quantities, which had been overlooked. Lime-water was added to the milk, and the medication consisted of Dover's powder, hydrarg. cum creta, an occasional dose of castor-oil, injections of laudanum, pepsin, bandaging the abdomen with flannel, cooling the head with frequent applications of cold water.

This treatment was continued for about a week, with some variations, and proving unsatisfactory, Dr. Underhill administered the sulphite of soda, according to the following formula:—

℞ Sodæ Sulphite, gr. xv.
Aquæ Puræ, ℥ j.

M.—One teaspoonful every three hours.

A little brandy, in a solution of gum acacia, was also given occasionally. The result within twenty-four hours was most gratifying, and in forty-eight hours a marked change for the better had taken place. From extreme exhaustion, insensibility to surrounding objects, and manifestation of great suffering, it lightened up and was disposed to notice and play with its older sister; its flesh became warmer and more firm, the discharges more natural in appearance and far less frequent—in fact, from a condition of most alarming character it rapidly changed to one of comfort and convalescence, and continued to improve daily until its health was perfectly established.

Dr. F. A. Burrall, New York, reports a case of *rupture of the heart* in a female, born in the United States, æt. 71, single. Patient had been suffering from occasional severe spasms of pain in the chest, but did not send for a physician. Was also in much mental depression. She had visited a friend on the previous day, and on returning in the evening suffered from nausea, prostration, and distress at the præcordia. She retired about midnight, and was found dead on the following morning. She lay upon her back, with the face thrown slightly to the right, the eyes closed, and the mouth open and *dry*. The expression was placid, and there was no appearance of a death struggle.

An autopsy showed an unusual development of adipose tissue. The stomach was much disturbed, the lungs and liver normal, the kidneys small and pale. The pericardium contained a large clot, and further examination showed an irregular rent in the left ventricle about one inch in length. On the inner surface of the ventricle, near the rupture, the muscular tissue seemed

eroded. The tissue of the walls was not examined microscopically, but was markedly fatty on ordinary inspection.

It would seem that there should *be no exudation from the mouth* in case of rupture of the heart, particularly if the rent were large, for a free passage being opened into the pericardium, engorgement of the lungs, or arrest of blood in them, would thus be counteracted. This condition would also diminish the probability of an exudation upon the surface of the bronchial tubes or into the mouth.

Dr. Robert Newman, of this city, considers *Désormeaux's Endoscope* a valuable assistant in the diagnosis and treatment of mucous linings, which otherwise would be hidden from ocular inspection. In granulations of the male urethra, female bladder and urethra, he applies local applications to the diseased parts—generally a strong solution of nitrate of silver.

If such applications are made carefully and intelligently, to circumscribed and diseased tissues only, they give no pain, and invariably cure chronic diseases of many years' standing. To prove this assertion he cites clinical facts, and besides hospital patients, reports forty-six registered cases, as follows: In the male—granular urethritis, 12; acute urethritis, 6; prostatic catarrh, 2. In the female—hæmaturia, with incontinence, 2; granular ulcerations in bladder and urethra, 3; chronic cystitis, with granulations, 7; granular urethritis, 7; urethritis with erosions, or simple ulcerations, 3; over-distention of bladder and enuresis nocturna, 1; calculus—phosphatic, 1; phosphatic incrustation and incontinence, 2.

To facilitate manipulations, Dr. N. has made many improvements and additional appliances to the endoscope. Details of cases, and the mode of manipulating the instrument for diagnosis and treatment, he has explained at length in his papers read before the Medical Societies of the States of New York and Connecticut.

From a number of cases reported by Dr. A. D. Rockwell, of New York, concerning the effects of the constant current on the great *sympathetic* in certain pathological conditions, we submit the following:—

The efficacy of galvanization of the cervical sympathetic in influencing the vaso-motor nerves, and thus reducing the volume of blood in the brain, was in a measure confirmed in the case of a gentleman of sixty years, who was suffering from hemiplegia of the left side. In the left eye there was a feeling of roughness as though a grain of sand was beneath the lid, owing to a decided and persistent injection of the conjunctiva. Under various methods of applying electricity, the patient slowly but manifestly progressed; but the injection of the conjunctiva, with the harassing sensation of roughness, yet remained.

Galvanization of the cervical sympathetic was then resorted to. This treatment, faithfully carried out, resulted in some general improvement; but the effect chiefly observed was an immediate diminution, and ultimately a cure of the chronic injection of the conjunctiva. The result in this case was of special interest and peculiarly suggestive, since it confirmed the deductions of physiological experiments on the effect of electrization of the cervical sympathetic in causing contraction of the arteriolas.

Dr. F. G. Snelling, of New York, reports *a case of pregnancy* dating from the wedding night, in which penetration did not take place until eight weeks after marriage; the semen meantime having been habitually lost at the ostium vaginæ. The testimony of both husband and wife upon the point is conclusive. There was great narrowness of the vagina, and tenderness of the vulva, and the husband was deterred from forcible efforts by the sufferings of his wife. Tardieu reports a similar case.

He also reports *an anomalous cause of death* in a case to which he was called in consultation. The patient, a young lady, died of wasting and inanition arising from difficulty of deglutition, which finally became impossible, for which no cause could be assigned. On making a post-mortem examination, no cause could be discovered to account for the symptoms, until, on removing the clavicles and dissecting about the lower part of the trachea, a small hard tumor was discovered which proved to be osseous in its character. It was about an inch long and half an inch in breadth and thickness; it was hard and solid, with numerous spicula of bone projecting from it longitudinally, and giving it much the appearance of a sequestrum. It was situated just above the bifurcation of the trachea, and inclined to the right side; a nerve was seen to be very intimately connected with the tumor, blended with its substance, and expanded over its anterior surface, which proved to be a branch of the pneumogastric nerve. A number of small spicula of bone were found among the numerous vessels and nervous filaments immediately surrounding the tumor. The tumor did not press upon the œsophagus, and was only loosely attached to the trachea. It was firmly adherent to the posterior surface of the vena cava superior.

By the interference of this tumor with the functions of the pneumogastric nerve was probably produced the peculiar difficulty of deglutition and accompanying disorders of digestion.

In regard to

"OXIDATION OF TISSUE AS THE SOURCE OF ANIMAL HEAT,"

Dr. Andrew H. Smith, of New York, writes as follows: The theory of Liebig, that animal heat was entirely the result of direct oxidation of the tissues through the medium of the oxygen brought to them by the blood, has been abundantly disproved by deductions from well-known facts.

Numerous other decompositions and recompositions, such as must take place in the body, are known to be sources of heat. Plants evolve heat when, under the influence of sunlight, they absorb carbonic acid and give out oxygen; while the moment this process is reversed, from the effect of darkness, the evolution of heat ceases. Thus *deoxidation* is here a source of heat, while *oxidation* is not. Moreover, the production of carbonic acid in the tissues does not require the introduction of oxygen from without, since the tissues already contain a supply, oxygen entering into the composition of every one of them. These, and many other considerations which might be adduced, show that the assumed analogy between tissue-change and combustion rests on a very insufficient basis.

But this idea is capable of refutation by direct experiment, which demonstrates that not only does the respiration of an increased amount of oxygen not produce an elevation of temperature, but that it actually may result in a decrease. To produce this effect, however, a considerable quantity must be inhaled, without being greatly diluted, as in the following experiment:—

At 4 P.M., having found that the thermometer in the axilla stood at 97.7°, Dr. S. inhaled for 15 minutes an atmosphere containing 70 per cent. of oxygen. The thermometer was then replaced in the axilla, and after a quarter of an hour indicated 97.3°. After a few minutes' interval the temperature in the clenched hand was taken, and found to be 97.2°. Without opening the hand the inhalation was resumed, and in 15 minutes the thermometer had fallen $\frac{6}{10}$ of a degree.

During the experiment the pulse fell from 80 to 64. At 10 P.M. the temperature in the axilla was still 97.3°.

These results coincide with those published by Mr. Savory in the *Lancet* some 12 years ago, as obtained from experiments on animals. Together with them they disprove the idea advanced by Priestley, that subjects inhaling oxygen would "live too fast," an idea which would deter from the use of oxygen in cases in which the temperature was already abnormally high. The decrease in the temperature agrees also with a fact which he had before observed, viz.: that the quantity of carbonic acid exhaled is notably diminished for a short time after respiring oxygen.

From an elaborate and able monograph, styled "Notes on the Physiology and Pathology of the Nervous System, with reference to Clinical Medicine," by Prof. Meredith Clymer, M.D., of this city, and reprinted from the *N. Y. Med. Journal*, we glean the following facts: *Disseminated Sclerosis* of the nervous centres may be described under three divisions, according to situation: Cerebral form; Spinal form; Cerebro-spinal form. It is doubtful if the *cerebral form* ever happens strictly alone. The only recorded observation is that by Valentiner and Frerichs. *Spinal Form.*—The invasion is usually very gradual, the first symptoms being tingling and numbness in one or both legs or soles of the feet, which are soon followed by weakness in the limbs; this last may, however, be an initial symptom. *Cerebro-spinal Form.*—The accession may be insidious, as in the preceding form, or abrupt. Simultaneously with, or foregoing, or following the motorial troubles, there are ocular or cerebral disorders, as constant vertigo, pain in the head, difficult articulation, weakness of sight, or diplopy; these are only transitory.

Differential Diagnosis.—This affection has sufficient individuality to secure its ready recognition, notwithstanding resemblances between its several forms and other diseases of the nervous system. Paralysis agitans, or shaking palsy, has been heretofore invariably confounded with this disorder. Paralysis agitans is chiefly met with in persons of declining years. Disseminated sclerosis of the cerebro-spinal centres is a disease of adult life. Nystagmus, so constantly present in sclerosis, is never met with in paralysis agitans. The intellect in paralysis agitans is generally unaffected until near the close, while in diffuse cerebro-spinal sclerosis it is mostly weakened from an early period.

Causes and Pathogeny.—It is essentially a disease of adult life. In the 18 cases collected by Bourneville, 14 were between 26 and 36 years of age; and of these 15 were females. In 13 cases there were: 1 physician, 1 theological student, 1 male teacher, 1 female teacher, 1 pianist, 3 seamstresses, 3 domestic servants, 1 truck gardener (female), 1 flower-woman.

The *pathogeny* of this affection, as well as that of other kindred diseases of the great nervous centres, is obscure and unsettled. May we not possibly find a truer interpretation of their nature by admitting their connection with and dependence on some latent but distinct condition of the constitution of the body, which favors the development of this peculiar form of morbid action? That they are simply varieties of chronic inflammation of the brain and spinal cord cannot well be admitted. They are more than this. The common assigned causes seem insufficient for their genesis, without some impalpable pre-existing tendency. May they not be, like Bright's and Addison's diseases, local expressions of a general state, in which a specific diathesis enters as an essential factor?

Prognosis.—No instance of recovery has been reported. It may be said to be incurable and progressively fatal.

Treatment.—Electricity, blisters, counter-irritants, ergot, arsenic, and belladonna have all been used without good effect. Strychnine temporarily modified the tremors in five cases. Nitrate of silver appears to have done the same, but it does harm if there is muscular contraction or clonic spasms. One case is reported as improved by tonics and sulphur baths. The constant galvanic current should in all instances be fairly tried.

Dr. Bradford S. Thompson, of New York, recommends *Brassica Rapa*—common round white turnip—in the treatment of cystitis resulting from the presence of calculi, and cites a case in point:—

Several years since a male, æt. 60, a resident of Columbia county, N. Y., suffering from the irritation of a large calculus, was operated on by a distinguished surgeon of this city for its removal, by the operation of lithotripsy. One or two particles of the calculus remained, and the old trouble in course of time revived in consequence of the gradual enlargement of the nuclei.

For several months the patient was much prostrated, and was treated by several practitioners, but not much relieved, until by accident he was advised to drink freely of a decoction of the common turnip, which gave great relief during the spasmodic attacks. Before taking this remedy he was confined to the house, but in a short time he was able to attend to business, and continued to do so until his death, from other causes, in 1869.

The preparation of the vegetable is simple—six turnips are put into two quarts of water, the whole boiled down one-half and then filtered. The patient should drink freely three or four times daily.

From observation and personal examination in this and other cases, your Secretary believes that this remedy, besides being a demulcent and antispasmodic, is a partial solvent of alkaline calculi.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MAY 25, 1870.

DR. A. L. LOOMIS, VICE-PRESIDENT, in the Chair.

(Continued from page 187.)

RELAPSING FEVER.

DR. WM. B. LEWIS exhibited two specimens from persons who had died at the Hart's Island Hospital of relapsing fever.

ACUTE TUBAL NEPHRITIS.

An aged German, of large frame, was admitted March 25th, when he was able to walk from the steamboat landing to the ward. On the following day he voided urine normally, and when seen in the evening was in an apparently good condition. At 2 P.M. on the 27th he was comatose, with tracheal râles and cold extremities. He died at 6 o'clock that evening.

At the autopsy the lungs, liver, spleen, and kidneys were found more or less diseased. The interest of the case, however, centres in the organs last mentioned. They were very large, and as torn from the lumbar region, of a blackish color, due to intense congestion. Upon section the color was found to be nearly as deep as that of the normal spleen, the cortical portion being ecchymotic in points, though generally of normal

consistence. The torn surface was at once bathed with blood. Capsule in parts firmly adherent, in others removed with slightly more difficulty than is natural. The renal pelvis contained a slight amount of turbid mucus, its membrane was injected to redness. The bladder was small, being firmly contracted, and contained about half a fluid ounce of transparent, high-colored urine. The intestinal mucous membrane was also of an intense dull-red color. There had been no diarrhœa or dysentery.

There are, if my information is correct, very few instances on record in which this fever has occasioned the disease of the kidneys here found. More or less congestion is very common, and suppression of urine is not rare; but the latter condition is generally dependent upon the existence of some form of renal lesion before the seizure with relapsing fever. Out of 14 cases in which I have made the autopsies, 3 have presented the symptom of total suppression of urine, but in this case alone was the disease producing that symptom of an acute character. In the others the renal disease was of long standing. On the other hand, in 18 fatal cases of which I have records, 17 pair of kidneys were decidedly morbid, and one only were normal, in respect to general appearances, excepting some congestion.

Microscopical examination shows the tubules to be generally densely packed with epithelium and blood, down to the apices of the pyramids. The vascular injection is also excessive. A portion of adipose tissue taken from the neighborhood of the pelvis exhibits the capillary supply of the parts in a manner which I have never seen equalled.

RUPTURE OF THE SPLEEN.

The second specimen is of even more interest, being the second on record from this cause, I believe, one other having been noted in Europe.

The patient from whom this was taken was 40 years of age, and mildly delirious, but without fever when admitted. The pupils and pulse were normal. On the 21st, rational at times; attributed his illness to drink.

22d. Delirium very active, but not violent; attendants constantly occupied in keeping him in bed.

On the following morning he died very quietly. The ward-master stated that he had neither fallen nor strained at stool, nor had undue force been used in controlling him. We cannot feel certain, however, that these statements are strictly correct.

Some urine removed at the autopsy was acid, sp. gr. 1012, albumen $\frac{1}{16}$, and contained numerous casts—hyaline, epithelial, and granular—many of them being greater than $\frac{1}{1000}$ inch in diameter.

VENEREAL DISEASE IN NEW MEXICO.—Dr. Andrew H. Smith, of N. Y., writes to the editor of the new *Indiana Journal of Medicine*, published in Indianapolis, as follows: Venereal disease is very rife in New Mexico—no class being exempt. Gonorrhœa is successfully treated by the natives with a decoction of an herb called *Malva*, but which is very different from the plant described by that name in works on materia medica.

The native inhabitants are a mixture of the Aztec with the Indian, the Spanish, and the negro. They present every shade of color, from that of the fairest Caucasian to the hue of the Hottentot.

The mean temperature at Fort Fillmore, for the 3 winter months, is 47°, for the spring months 64°, for the summer months 81°, and for the autumn months 64°.

Medical Items and News.

HOUSE STAFF OF BELLEVUE HOSPITAL FOR 1870.—*House Physicians*—Charles W. Bedeau, John J. Reid, W. M. Polk. *Senior Assistants*—S. D. Powell, B. D. Taylor, Walter Judson. *House Surgeons*—John G. Curtis, Charles McBurney, N. G. McMaster. *Senior Assistants*—J. D. Bryant, J. T. Synnott, W. O. Byrne. *Junior Assistants*—S. B. St. John, W. T. Alexander, T. K. Cruse, William D. Schuyler, F. G. Metcalf, M. G. Millikin.

ALUMNI ASSOCIATION OF BELLEVUE HOSPITAL MEDICAL COLLEGE.—At the recent annual meeting of this association the following officers were elected for the ensuing year:—*President*, Dr. James F. Ferguson, New York. *Vice-President*, Dr. Lucius B. Irish, Brooklyn, L. I. *Recording Secretary*, Dr. Reuben A. Vance, New York. *Corresponding Secretary*, Dr. F. H. Bosworth, New York. *Treasurer*, Dr. Henry Raphael, New York. *Executive Committee*—Drs. William T. Lusk, Leroy M. Yale, E. L. Mola, F. A. Castle, T. R. Pooley, Charles A. Searle, New York; George W. Terriberry, Paterson, N. J.; J. W. Pinkham, Montclair, N. J.; P. R. Cortelyon, Brooklyn, L. I.; Jos. Cushman, T. M. P. Cross, Bradford S. Thompson, New York; and Ira B. Read, Harlem, N. Y.

N. Y. STATE LUNATIC ASYLUM, UTICA.—The Twenty-seventh Annual Report of the managers of this flourishing institution, for the year 1869, exhibits the following facts:

	Men.	Women.	Total.
Number of patients at the commencement of the year	284	286	570
Received during the year	251	212	463
	535	498	1,033
Discharges, recovered	81	75	156
" improved	38	47	85
" unimproved	72	45	117
" not insane	7	1	8
Died	38	26	64
Whole number discharged	236	194	450
Remaining November 30, 1869	298	305	603

Of the 463 admissions, 133 were insane from two to twenty-eight years. Among those admitted there were 29 paretics, 10 epileptics, 2 imbeciles, and 1 paralytic. Twenty-seven were between sixty and eighty years of age. In the great majority of cases insanity was due to physical causes.

Dr. John P. Gray, the efficient superintendent, alludes to the visit of Dr. Henry D. Noyes, of New York, at the Asylum, and thanks the Professor for the instruction in the use of the ophthalmoscope. His brief clinic was most interesting, highly instructive and useful. The superintendent anticipates valuable results in diagnosis and prognosis from ophthalmoscopic investigations. In cases of paresis, embracing all stages of the disease, Prof. Noyes found in each case a lesion of the optic nerve and vessels characteristic of each stage of the disorder. Thus far all efforts to arrest the progress of paresis, except temporarily, have proved unavailing. Dr. Gray considers the relation of phthisis to brain disease one of the most interesting and important questions of research, and he has long thought the condition of the circulation a most important field of study, and believes the sphygmograph to be a valuable aid to physical diagnosis.

Rhode Island Medical Society.—The Fifty-ninth Annual Meeting of the Rhode Island Medical Society was held at the Franklin Society Rooms, on North Main street, Providence, Wednesday morning, June 8th, and was attended by a large number of the members of the Society from the city and other parts of the State.

The President, Dr. J. W. C. Ely, called the meeting to order at 10 o'clock, and the proceedings of the last annual meeting were read by the Secretary, Dr. Geo. E. Mason, and approved.

The annual reports of the several standing committees were presented, read, received, and ordered to be placed on file.

The Board of Censors having held their usual meeting previous to the organization of the annual meeting, Dr. Sylvanus Clapp, Secretary of the Board, read the annual report, which was received and ordered on file.

On recommendation of the Board the following named gentlemen were elected Fellows of the Society: Dr. Gustavus Radeke, Dr. Charles H. Leonard, Dr. Thomas Maher, Dr. Albert E. Ham, all of Providence. Dr. Alonzo Clark, of New York, was elected an honorary member.

The Treasurer, Dr. T. K. Newhall, presented his annual report, which was read, accepted, and ordered on file. Receipts, including cash in treasury at last annual meeting, $402.24. Expenditures, $410.59.

Dr. Otis Bullock, of Warren, delegate from this Society to the last meeting of the American Medical Association, held at Washington, D. C., in May, made a report to the Society of the proceedings of that Convention.

Dr. G. L. Collins proposed sundry amendments to the by-laws of the Society, which were read, and, on motion, were adopted.

The President, Dr. Ely, appointed the President and Secretary elect a committee to superintend the printing of a new and revised edition of the charter, by-laws, and a list of members of the Society.

Dr. S. A. Arnold, Secretary of the Trustees of the Fiske Fund, read the annual report of the Board, which was received and ordered on file. No prize was awarded for an essay received during the past year. The Trustees offer the following prizes for the year 1870:—

First—Ununited Fractures. The conditions under which they occur, and the most successful method of treatment.

Second—Hydrate of Chloral. Its physiological effects and therapeutical uses.

For the best dissertation on each or either of these subjects, the Trustees will pay the sum of one hundred dollars. Essays must be sent to the Secretary of the Fiske Fund Trustees, Dr. S. A. Arnold, on or before the first day of May, 1871.

The Society then proceeded to the annual election of its various officers by ballot, as required by the by-laws, and the following-named gentlemen were elected for the ensuing year, Dr. Ely having declined a re-election:—

President—Dr. George L. Collins, of Providence.

First Vice-President—Dr. Lloyd Morton, of Pawtucket.

Second Vice-President—Dr. Fenner H. Peckham, of Providence.

Recording Secretary—Dr. Clarence T. Gardner, of Providence.

Corresponding Secretary—Dr. Chas. W. Parsons, of Providence.

Treasurer—Dr. T. K. Newhall, of Providence.

Board of Censors—Drs. T. C. Dunn, Newport; Ariel Ballou, Woonsocket; Charles Fabyan, Providence; Otis Bullock, Warren; Sylvanus Clapp, Pawtucket; James Millar, North Providence; J. W. C. Ely, Providence.

Committee on Registration—Drs. E. M. Snow, E. T. Caswell, Providence; S. Clapp, Pawtucket; James H. Eldridge, East Greenwich; T. C. Dunn, Newport.

Committee on Publication—Drs. Geo. E. Mason, H. G. Miller, A. R. Becker, Providence.

Audit Committee—Drs. C. W. Parsons, Chas. Fabyan, Providence.

Dinner Committee—Drs. J. W. C. Ely, T. K. Newhall, Providence.

Dr. C. W. Parsons read a communication from a committee of the American Medical Association, on the subject of an annual medical registration, which was referred to a Special Committee, consisting of Drs. S. Clapp, E. T. Caswell, and Geo. P. Baker.

Dr. Geo. H. Church, of Wickford, being over 70 years of age and out of practice, was excused from further payment of the annual Society tax in accordance with the by-laws.

Dr. Geo. E. Mason, Secretary, read a well-written eulogistic obituary essay upon the late Hon. Henry Halsey Childs, M.D., of Pittsfield, Mass., prepared by Dr. S. Clapp, of Pawtucket, which was received, and, upon motion, referred to the Committee on Publications.

The Secretary also read a petition to Congress, praying that body to establish the rank of the medical officers of the United States Navy, which was signed by many of those present, and will be forwarded to the Senators from that State for presentation in Congress.

Dr. Robert Millar, of Providence, was appointed Orator, and Dr. A. R. Becker, Substitute, and Dr. Chas. W. Parsons, of Providence, Anniversary Chairman for the next annual meeting.

Drs. S. S. Keene and C. T. Gardner were appointed to prepare papers to present at the next quarterly meeting of the Society, which was appointed to be held in Woonsocket, on the third Wednesday in September.

Dr. Charles O'Leary was appointed Orator for the meeting in December.

Dr. Corliss, delegate from the Medical Society of the State of New York, was introduced and addressed the Society.

The annual dinner was served at the Aldrich House.

The Home for Incurables.—The third anniversary of the Home for Incurables, took place June 11, 1870, at West Farms, Westchester County, N. Y., where the Home is located. The anniversary exercises were held in the Reformed Dutch Church, of West Farms, and were opened by prayer by Rev. Mr. Chamberlain, of Morrisania. Dr. Rodman, the superintendent, then read the annual report, from which it appeared that the Home has at present thirty-five patients. The larger part of the incurable diseases represented are consumption, cancer, and paralysis. After reading the report the audience was addressed by Rev. Drs. Washburne, Vermilye, and Potter, of New York City. Dr. Washburne, who was one of the founders of the Home, alluded to the meeting in the house of Mr. Randolph, three years ago, when the scheme for founding the institution was first inaugurated.

Lunatic Asylums in the State of New York.—The establishment of a third general hospital has been ordered by the Legislature, and has been located at Buffalo. We now have the asylum at Utica for Central, the Hudson River Hospital at Poughkeepsie for Eastern, and the institution at Buffalo for Western New York, and the Willard Asylum for chronic insane.

HUDSON RIVER STATE HOSPITAL FOR THE INSANE.—From the Third Annual Report of the Managers of this Institution—now being erected at Poughkeepsie, N. Y.—we learn that $150,002.21, have been expended thus far on the two unfinished sections. When finished, a population of not less than eighteen hundred thousand persons will be entitled to its privileges, none of whom are more than eighty miles distant from its doors. Dr. J. M. Cleaveland, formerly of Utica, is the Superintendent.

HOSPITALS AND DISPENSARIES IN MANCHESTER, ENGLAND.—This English city, with a population of less than half a million of inhabitants, has sixteen hospitals and public dispensaries.

RESULTS OF SURGICAL OPERATIONS WITH AND WITHOUT ANÆSTHETICS.—Prof. Simontin, of Nantes, has performed 250 operations during the last 34 years. Of these the results in amputation and hernia are as follows: Amputation of the thigh without anæsthetics, 7, with 4 deaths, or 57 per cent.; with anæsthetics, 23, and 8 deaths, or 35 per cent. Amputations of the leg, 11, and 5 deaths, without anæsthetics, or 45 per cent.; and 14, with 3 deaths, or 21 per cent., with them. Strangulated hernia, 25 operations and 9 deaths (36 per cent.) without, and 10 operations with 1 death, or 10 per cent., with anæsthetics.—*Med. Times and Gazette.*

IMPORTANT REMEDIES.—Dr. C. Drysdale (*Med. Times and Gazette*) finds that the most valuable articles in the Pharmacopœia in the treatment of cases coming under his care in the North London Consumption Hospital, are the perchloride of iron, iodide of potassium in large doses, and cod-liver oil.

THE ADMINISTRATION OF CHLOROFORM IN THE RIGHT-ANGLE KNEE AND CHEST POSITION. — Dr. Nathan Bozeman, of New York (*Am. Jour. of Obstetrics*), endorses the knee and chest position in surgical operations of the female, which has been employed in Europe for more than half a century. He has had chloroform administered in this position more than fifty times during the last two and a half years, and without one untoward symptom.

In his improved knee and chest position every operation can be performed, in every case, with or without anæsthetics. He adds, in closing: "Fulfilling every indication, it leaves nothing to be desired."

THE HISTORY OF THE OPERATION OF THE CÆSAREAN SECTION.—According to Prof. T. Gaillard Thomas, M.D. New York (*Am. Jour. of Obstetrics*), this operation was practised among the Jews; it was a recognized operation during the Greek civilization, and during the Roman it received the name under which it is known to us. The first case in which it was resorted to in later times for removal of a child from the body of a living woman, which can be regarded as really authentic, dates back only to about the period of the discovery of this country, 1491.

BLEPHAROPLASTIC OPERATION.—Dr. Eve, St. Louis (*The Medical Archives*), reported to the St. Louis Medical Society an interesting case of blepharoplastic operation on the left eye, on a patient 22 years of age, for the relief of a cicatricial deformity following a burn received from falling into the fire during a fit when a child. The relief from the deformity was regarded as almost perfect.

INFANT MORTALITY.—In 1868, 203,129 children died in England under five years of age.

A PRECOCIOUS MOTHER.—The Registrar-General of England reports the case of a daughter of an Essex laborer who gave birth, in 1869, to a child before she was eleven years of age.

CASUALTIES IN JAVA.—During the year 1869, in Java, 183 men, 53 women, and 38 children were killed by tigers, 158 persons by crocodiles, and 22 by snakes.

This is nearly as bad as the mortality caused by horses driven by tipsy cabmen and careless butcher boys in the streets of this city and London.

THE CONVENTION OF MEDICAL SUPERINTENDENTS FOR THE INSANE.—This Convention was held this year in Hartford, Conn., and adjourned Saturday, June 18th. The next meeting will be held in Toronto on the first Tuesday in June, 1871.

SUBSTITUTE FOR WASHING SODA.—A German journal recommends laundresses to use hyposulphite of soda in place of common washing soda. It does not attack the fabric in any way, and at the same time exerts some bleaching action, which greatly improves the appearance of linen and calicoes.

PROGRESS OF MEDICINE.—The annual address before the Medical Society of the State of New York, on "Progress of Medicine," by Prof. James P. White, M.D., of Buffalo, President, on February 2d, 1870, has come to hand, and is well worth perusing. Those who have asserted that the profession is *non-progressive* will do well to carefully read this sound and practical address on the advancement made in medicine within the last forty years.

SIMS'S SPECULUM.—M. Schuppert, of New Orleans, La., affirms that the so-called Sims's speculum was invented by Metzlar, of Prague, in 1846.

THE BENEFITS OF A SEA VOYAGE.—A patient writes to the editor of *The Pacific Medical and Surgical Journal*, from the Sandwich Islands, commending the sea voyage to those afflicted with chronic diarrhœa. In his case, the voyage from San Francisco to these islands cured the chronic diarrhœa, which had resisted all treatment. He recommends the climate of the Sandwich Islands to invalids with diseases of the digestive system.

DECEASE OF AN ELECTRO-THERAPEUTICIAN.—Dr. Morpain, of Paris, so widely known for his researches in electro-therapeutics, died a few days ago. Remak's work was translated by this author.

NEW YORK ACADEMY OF MEDICINE.—At a recent meeting of the Academy, Bradford S. Thompson, M.D., was elected Resident Fellow.

SAN FRANCISCO MICROSCOPICAL SOCIETY.—This new society has elected the following corresponding members: Drs. J. W. Deems and Arthur M. Edwards, of New York.

A FAT MISS.—Ohio county, Indiana, boasts of a girl named Susie Ellenwood, æt. 12, who has attained the enormous weight of 282 pounds.

A SOUTHERN GIANT.—A man in Orange county Florida, is said to measure 9 feet 6 inches in length.

QUINIA IN SEPTIC AFFECTIONS.—One of the first contributions of recent times on the therapeutic powers of quinine in septic affections, was written by Gieseler.

THE IMPORTATION OF HEIFERS FOR VACCINATION PURPOSES.—Dr. Martin, of Boston, asked and received permission to import, free of duty, four heifers from France, for the purpose of obtaining virus for vaccine purposes, on the ground that virus from heifers in this country is impure.

IODINE SPRING.—A valuable iodine spring has lately been discovered near the city of San Francisco, Cali-

fornia. The *savants* of the golden city are engaged in the analysis of the water, which contains so much iodine that it gives without condensing a strong reaction when the proper test is applied.

California Pharmaceutical Society.—This flourishing society has received a gift of a collection of two thousand botanical specimens from Calaveras county, Cal. These were gathered and presented by Mr. T. J. Searle, now of the Sandwich Islands.

Pertussis.—From a work on "Diseases of Children," by Drs. J. Forsyth Meigs and William Pepper, of Phila., we glean the following, with reference to the management of pertussis: Alum is the favorite remedy; belladonna and sulphate of zinc, carbonate of potash and opium come next; but the favorite prescription is 1-24 of a grain of the extract of belladonna, and one grain of alum three times daily, to a child of three months.

The Spread of Cholera.—Dr. Matthews Duncan, of Edinburgh, states that the spread of this fatal disease was often traceable to the throwing out of the stools into back gardens and middens adjoining houses, their gaseous matters poisoning the atmosphere, and their fluids percolating into the wells, and so reaching the neighboring inhabitants.

A Quick Payment.—Hahnemann, the founder of homœopathy, on being consulted by an English peer, gave his patient a smell from a small vial and assured him he was cured. "What's the bill?" asked the astonished nobleman. "One thousand francs." The visitor pulled out a roll of bank-bills and held them under the doctor's nose, saying, "Only one smell; you are paid."—*Mich. University Med. Journal.*

The First Ligator of Arteries.—Although Ambrose Paré claimed the use of the ligature as his discovery, Galen, after using cold water and astringents, remarked, "he raised the bleeding vessel by means of the hook and secured it by a vinculum or ligature."

The Use of Forceps in Labor.—The *Philadelphia Reporter* copies from the *British Medical Journal* the following from Dr. Thomas Savage: "It seems remarkable that, until quite recently, so few practitioners should have advocated the more frequent use of forceps in midwifery, except in difficult cases such as the older writers describe. Dr. Steele says: 'The second stage of labor ceases to be actively progressive, excepting, of course, when contraction or distortion of the pelvis necessitates turning or craniotomy, or where the os uteri is only partially dilated and at the same time undilatable.' My own experience, though limited, is so decidedly in favor of this practice, that I have concluded to record it, and do so as follows: During five years I attended 807 cases, and used forceps 104 times. Of these 807 cases five were still-born, and one natural death occurred from puerperal fever, which was in no way traceable to the means used to accomplish delivery. In comparison with this record I give the statistics of the Royal Maternal Charity, as quoted by Dr. Ramsbotham, where out of 48,996 deliveries, forceps—long and short—were used 73 times, or once in 671.2 cases, and of these 73 applications 15 were stillborn, thereby showing that their use was not resorted to until the head had been for a long time subjected to successive pressure. In none of my cases have I found any ill effects afterwards, such as laceration of the soft parts, rupture of the perinæum, &c., and I cannot but believe more children would have been stillborn if instrumental aid had not been given. The occipito-posterior presentation appears to offer the most difficulty in effecting delivery, and Tyler Smith says that these cases should be slowly rotated during the process of extraction, so as to bring the vertex towards the pubic arch, and thus convert them into occipito-anterior presentations; a proceeding which to myself has seemed very easy in a diagram, but attended with some difficulty in practice."

The Heart's Labor.—The total daily work of the human heart is equal to 124,208 tons of 2,240 pounds each, lifted one foot. Prof. Haughton, of Dublin, states that if the heart should expend its entire force in lifting its own weight vertically, it could raise that weight 19,754 feet in an hour.—*Jour. of Chemistry.*

Torsion of Arteries.—Arrest of hemorrhage by torsion of arteries, is quite popular in Steevens' Hospital, Dublin; it has been resorted to in cases of amputation at the wrist, ankle, and leg, below the knee.

Herr Radienbacher.—This distinguished Professor of Chemistry in the University of Vienna was stricken down with apoplexy a few days ago, and died at the age of sixty. Since 1839, he had been connected with the University.

A Case of Spontaneous Ptyalism.—An aggravated case of this character is related by C. W. Knight, M.D., U. S. A., of Post Lampasas, Texas (*Med. and Surg. Reporter*), which was successfully treated by a saturated solution of chloride of sodium, and crystal of rock salt topically, and a tonic regimen.

He calls it spontaneous ptyalism after Dr. Thomas Watson, who gives, in his "Practice of Physic," that name to a similar train of symptoms.

N. Y. State Lunatic Asylum.—The whole number of patients admitted to this Asylum since its opening is 9,225; and of these 3,572 recovered, and 1,407 were discharged so far improved as to return to their usual duties.

Vaccination First Introduced into Hindostan.—Rev. J. A. Dubois, an English missionary, introduced vaccination into Hindostan in the year 1802. At first the natives imagined that the English wished to affix an indelible mark on certain persons; and all males so impressed were, when they grew up, to be forced into the military service, and the females to be concubines.

A Button in the Larynx Removed by Suction.—A case of accidental introduction of an ordinary shirt button into the larynx is reported by Dr. Rumbold, of St. Louis (*The Med. Archives*), and its removal by suction by means of an elastic tube armed with an exhausting apparatus.

Alcohol an Anæsthetic.—Dr. B. W. Richardson, of London, regards alcohol as strictly anæsthetic, and mentions the first published case of surgical operation under anæsthetic sleep, in 1839, by Dr. Collier, on a negro, who was rendered insensible by breathing the fumes of alcohol. The anæsthesia is too slow and prolonged for ordinary surgical operations.

Aneurism of the Mitral Valve.—At a meeting of the San Francisco Medical Society on the 12th of April, Dr. Edwin Bentley, Asst. Surg. U. S. A. (*Pacific Med. and Surg. Journal*), exhibited a pathological specimen of this rare affection, taken from a male patient, admitted into the San Francisco City Hospital, March 25, and died April 6.

Aneurism of the mitral valve is a rare disease, and was first pointed out and demonstrated by Dr. Thurman, in the "Medico-Chirurgical Transactions," vol. xiv.

Lecture III.

PROGRESSIVE MYO-SCLEROSIC PALSY.

Definition—By whom first described—Duchenne's claims—The cases reported in Germany—Clinical History—Three Stages—Electric Exploration—Patho-anatomy—Histology—Nature and Causes—Differential Diagnosis—Duchenne's trocar—Prognosis—Treatment. (*Seven Illustrations.*)

I PROPOSE in this lecture to treat of an affection which has only quite lately been recognized and studied, and about which but little is generally known, namely, *progressive myo-sclerosic palsy*, called also *pseudo-hypertrophic paralysis*, and by the Germans *progressive muscle-hypertrophy*. Until recently it has been confounded with other forms of infantile palsy accompanied with structural changes in the affected muscles.

It may be defined as a progressive disease of childhood, of successive stages, beginning with muscular weakness in the lower limbs, a characteristic wabbling gait and well marked anterior sacro-lumbar curvature; the paretic muscles, particularly the gastrocnemii, are after a while greatly increased in size, but in time become atrophied, and lose all motor power; no constant cerebral symptoms happen in the course of the disorder, and the general health continues good until the last stage; no lesion of the nervous centres has as yet been made out, and its anatomical character may be stated therefore as overgrowth of the interstitial muscular connective tissue and subsequent fibroid substitution, with consequent suppression of the proper sarcous or contractile element; in some instances there have been large fatty accumulations in the fibrillary interspaces, probably the result of regressive degeneration.

The first recorded case of this form of palsy which I can find is by Dr. Edward Meryon, who on the 9th December, 1851, read a paper before the Royal Medical and Chirurgical Society, in which he described the history of a child who, born healthy and well-proportioned, walked late, and then clumsily until eight years of age, when his walking gradually worsened, and at eleven he could not walk at all, and could scarcely stand. At about twelve years old the power of the muscles of the upper extremities began to lessen also, notwithstanding that the muscular mass of the body and limbs did not appear to have diminished; on the contrary, the child had grown well and had gained flesh. When fourteen he died of fever, and on examination the spinal cord was natural, but all the voluntary muscles were atrophied and soft; and although the muscular fibres appeared to exist, they were almost bloodless. Under the microscope the striped elementary fibres were found to be completely destroyed, the sarcous element being diffused, and in many places converted into oil-globules and granular matter. The changes were most advanced in the muscles of the abdomen and legs. Dr. Meryon likened the condition to the fatty disease of the heart described by Dr. Richard Quain. He further states that three brothers of this patient, born later, were similarly affected. And he mentions also that Dr. W. Bullar, of Southampton, had told him of two cases, which, from their clinical history and the post-mortem appearances in one of them, were probably like. The fact of "the calves being larger than natural," and having during the progress of the disease become permanently contracted, is particularly noted. Dr. Meryon adds that two other similar cases had come under his notice during that year. In the thirty-seventh volume of the Medico-Chirurgical Transactions, 1854, Dr. T. King Chambers reports a kindred case, in connection with mollities ossium; a microscopic examination of a portion of the rectus femoris muscle showed that it had become "a mere congeries of fat-vesicles, the interspaces between which were filled up with globular granular corpuscles."

I have been thus particular in mentioning these cases of the English physicians, and of whose identity with the disease I am about to describe I have no doubt, because Dr. Duchenne (de Boulogne) insists that "the glory of this discovery belongs unquestionably alone to France," or rather to himself, though his first case was in 1858, and his first published account of it in 1861 (*Electrisation Localisée*, 2ième ed. 1861.) This eminent physician is possessed, like Lamartine, with the conviction that when a new idea is to be communicated to the world it is always put first into the head of a Frenchman. Still much credit is due to Dr. Duchenne for his intelligent study of this affection, and his individualization of it as a separate form of the muscular palsies, in his admirable papers in the *Archives Générales*, in 1868. He unquestionably set it before the profession as a distinct disease, and directed attention specially to it. He gives in detail twelve cases which had come under his observation, with mention of others; and you will see in the course of this lecture how much we are indebted to him for his clear interpretation and valuation of its clinical history.

From 1862 to the present time cases have been published by Jaksch, Berend, Eulenberg and Cohnheim, Wernich, Oppolzer and Stopella, Griesinger, Heller, Seidel, Leyden, Wagner, Benedikt, and Lutz, in Germany; Spielman and Schutzenberger, and Bergéron, in France; and Meryon (1866), Hillier, W. Adams, Foster, and Russell, in England. The first systematic article on the subject in English I published in 1868, in an appendix to the second American edition of Dr. Aitkin's "Science and Practice of Medicine."

There are three stages of this disorder: (1.) That of paresis, shown by weakness of the lower extremities, side-to-side balancing in walking, the legs being wide apart, with a marked anterior arching in the sacro-lumbar region (lordosis) in standing and walking, with persistent rigid flexion, or clawing, of the toes. (2.) Increased volume, a hypermegalia, of the muscles of the legs, particularly of the muscles of the calves, and of the glutei, and of the back, which are large, elastic, and very firm. This stage is generally for a while stationary, and may last for several years. (3.) Then generalization and progressive aggravation of the palsy, followed quickly by muscular atrophy, the patient becoming bedridden, and dying either from some intercurrent disorder, or from systemic deterioration and exhaustion.

Let us briefly examine in detail these several stages. 1. The initial symptom is the muscular weakness in the legs. There are no necessary prodromic phenomena. No pain in the limbs is complained of by the little patients; the onset is in the midst of apparent health. In two only of the recorded cases had there

been previous convulsion-spells, but the connection between them and the disease does not appear. The child becomes easily tired, walks clumsily, or topples over readily, cries or begs to be carried, and is unwilling to walk. If quite young, the paretic state of the limbs may be overlooked, until the backwardness in walking is noticed. But in these cases it will be found that it does not kick and move about its legs naturally and actively. When the limbs are examined they seem well made and firm. In children who have already walked, the peculiar, characteristic wabbling gait often first attracts notice. This side-to-side balancing is necessary to enable the child to keep its equilibrium when in motion. The legs are widely apart, and the little patient waddles like a gobbler. In spite of ridicule or punishment this gait is necessarily persisted in, and daily becomes more emphasized as the weakness of the back and buttocks increases. Now if you examine the spine when the child is standing or walking, you will discover a sacro-lumbar curvature, varying in degree from a slight bending forward to a deep saddleback (Fig. 1).

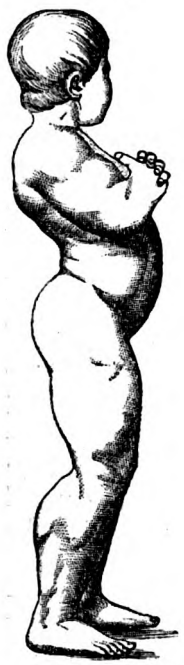

Fig. 1. Side view of a boy, æt. 10, with myosclerosic palsy, showing sacro-lumbar curvature in walking and standing. (Duchenne.)

Fig. 2. A side view of a boy, æt. 7, with myosclerosic palsy, showing saddleback, and fall of plumb-line touching the dorsal spinous processes and falling outside of sacrum. (Duchenne.)

This curve of the vertebral column is the result of weakness of the extensor muscles. It is caused by the effort to keep the upright position, the line of gravity being maintained by the support given by the abdominal muscles. This Dr. Duchenne proved by making the patient stand erect, at the same time preventing the spinal bend; the trunk directly fell forward, and the hands were placed at once on the thighs and legs to hinder falling over. In the photograph I now show you (Fig. 2) you will see that the plumb-line A, which touches the spinous processes of the dorsal vertebræ, falls far outside of the sacrum. In cases where a deep sacro-lumbar curvature exists from weakness of the abdominal muscles, a plumb-line similarly applied falls over the centre of the sacrum. In some cases quite early in the first stage there is a slight pointing of the foot; generally this happens later, and it increases until the heel is drawn up and there is complete equinism (equino-valgus) of both feet. The plantar arch is more or less effaced, the position of the first phalanges to the metatarsal bones is unnatural, whilst the toes are permanently bent, and look like claws. Flexion of the foot is difficult or nil, whilst extension is easy and often forcible. This condition is due to the damage of the contractile tissue of the flexors.

2. The second stage is marked by the striking feature of this curious disease, namely, the apparent bilateral hypertrophy of certain muscles, which appears at a variable period after weakness of the lower limbs, usually from a few months to one year. Any of the muscles may become affected, but it generally begins in the gastrocnemii, and in the muscles of the thigh, and in the glutei; then the muscles of the back and belly, particularly the oblique abdominal, the biceps, deltoid, and sometimes the muscles of the face, especially the temporal. In Eulenberg's case, where the disease began at five years of age, this muscular hypermegalia came on at ten in the muscles of the thigh, those of the leg were next invaded, and finally the triceps brachialis. In Oppolzer's, reported by Stofella, a considerable period elapsed before the muscular development was apparent; when the gastrocnemii contracted they formed two masses nearly the size of a man's fist. Though in most instances the apparent hypertrophy is limited to the muscles already mentioned, it may extend to others. In Bergéron's case it involved the muscles of the face, particularly the temporal, those of both extremities, and of the trunk, except the great dorsal, pectoral, and the sterno-mastoid of the neck. The boy, when ten years old, had the appearance of an exaggerated Farnesian Hercules, weighing about eighty pounds.

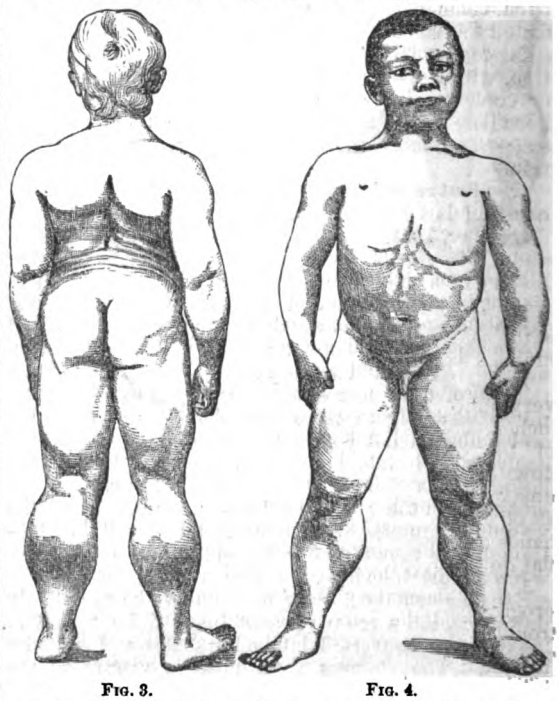

Fig. 3. Fig. 4.

This photograph (Fig. 3) represents the back view

of a boy, ten years old, with this disorder, and exhibits the general muscular enlargement, giving to him the appearance of a young athlete. Here is another (Fig. 4), a front view of the same patient, in which you see that though nearly all the muscles of the body are apparently hypertrophied, the pectorals are atrophied. It gives, too, a good representation of the position of the legs in standing and walking. Both are from Dr. Duchenne's photographs.

In one case, Dr. Duchenne thought that the paresis and hypertrophy were coincident, but this seems doubtful. Whilst some of the muscles are thus hypermegalic, others may be attenuated; thus the lower limbs may be over-sized and the upper positively emaciated.

In this photograph (Fig. 5) all the muscles of the lower extremities, together with the glutei and lumbar, are of enormous size, and contrast markedly with those of the disproportionately sized arms. In the other one (Fig. 6) the gastrocnemii are alone enlarged in the lower extremities, with the glutei and lumbar, and the arms look very thin.

FIG. 5.

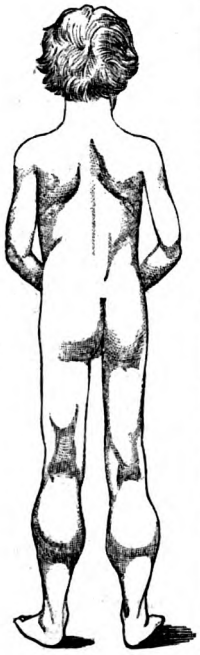

FIG. 6.

When we come to describe the anatomical characters of this affection, the structural condition of the enlarged muscles will be studied and illustrated.

In the advanced stages the erect position becomes very difficult; the feet are widely separated, say to ten inches; and the patient stands and walks on the ball of the toes; even when supported he cannot bring down his heels to the ground. The equilibrium is so unstable that the slightest push upsets him, and he falls all of a heap. The progression is often slowly on the hands and knees, the palms, like a forepaw, being placed flat on the ground.

3. I have placed myo-sclerosic palsy amongst the progressive disorders, and we have seen the functional troubles of the first stage increase during the second, or period of full development, but the fastigium being reached, there is a pause, which may last for several years—two, three, or even many more; the symptoms are stationary, they neither worsen nor get better. Sudden and rapid aggravation of some of the existing troubles then happens, and new ones set in; the paralysis now extends to the upper extremities, if it has hitherto been limited to the lower, the use of the arms is lost, the muscles generally become atrophied, there is great emaciation, and the helpless patient is nailed to his couch or bed; finally the health, hitherto good, breaks, and some intercurrent disease, as bronchitis, or pneumonia, or tubercle, kills before adult age is reached, or death follows from general debility and exhaustion.

There do not seem to be any marked or uniform brain-troubles throughout the course of the disorder. Most of the patients are dull, heavy, indolent, and apathetic, and the intellect is often sluggish and the speech hesitating; but this is by no means constant. One of Duchenne's cases was an idiot, another nearly so. Ophthalmoscopic examination has so far been negative. The body-heat and the circulation are unaltered; even the temperature of the affected limbs and their capillary circulation being unaffected. Several exceptions, however, have been reported: one by Griesinger, in a lad thirteen years old, whose limbs, especially the lower ones, had a rosy tint, with increased temperature; and when these parts were uncovered to the air and exposed, after a little while they became more or less blue and marbled, with decided loss of heat. This condition came on spontaneously, or when making an effort to move the limbs. In a man of twenty, attacked two years previously, the right side of the face had more color than the left, with more abundant sweat secretion, and dilatation of the right pupil. Pressure on the right cervico-sympathetic region was painful, and all these symptoms disappeared after galvanization of the nerve. In Dr. Foster's case the integument of the lower extremities was remarkably mottled, patches of purplish color alternating with white. In one of Dr. Russell's cases it was the same.

Pain in the limbs or in other parts of the body is rarely complained of, even during passive motion of the affected extremities, but occasionally there is a feeling of considerable tension produced in the antagonist muscles in any attempt at motion; for example, in trying to forcibly bend the leg the flexors of the knee-joint may be thrown into a state of tonic spasm, causing some degree of pain. Neither hyperæsthesia nor anæsthesia, deep-seated or cutaneous, has been remarked. The functions of the bladder and rectum are usually intact, unless towards the terminal period.

The effects of electric exploration on muscular contractility and irritability would seem to vary with the kind of current used. With the exception of Eulenberg's case, muscular contractility was always lessened when tested by faradism, and that not only in the enlarged muscles, but in those whose size remained unaffected. Electro-muscular sensibility is uncertain; it may be natural or lessened, or it may vary at different times in the same case. In Wagner's case, where the constant current was alone employed, muscular irritability and contractility were unaffected. Benedikt and Stofella made comparative examinations with both the faradic and continuous currents; faradism showed diminution of electro-muscular contractility, whilst galvanism in the course of the nerves of the muscles from the spine was followed by either natural or exaggerated contractions.

With regard to the *patho-anatomy* of myo-sclerosic palsy, in the only post-mortem examination that I know of where the brain and cord were examined microscopically by skilled observers—that of Eulenberg and Cohnheim (1865)—no coarse change was found.

With respect to the muscle-tissue, we have seen what was its condition in Dr. Meryon's cases. In Griesinger's case, Prof. Billroth removed during life a small piece of the left deltoid, which was paralysed and apparently hypertrophied. The primitive fasciculi were whole, but were shoved apart by a large quantity of adipose material; there was no trace of fatty degeneration in the fibre. Wernich took a small piece of the gastrocnemius from a lad of eleven years with the disease, and, examining it microscopically, saw nothing structurally anormal, but large masses of fat were deposited between the fasciculi. Heller found the fatty vesicles in such quantity in the fibrillar interstices that he proposed to call the disease lipomatosa luxurians. In Eulenberg and Cohnheim's case the fibres in some of the damaged muscles were much atrophied, reduced a fifth or sixth of their natural size, and with little masses which seemed to be empty sarcolemmata; throughout there was fatty matter, which in some places could not be distinguished from subcutaneous adipose tissue. In all of Dr. Duchenne's cases in which the muscles, whether hypertrophied or not, were examined, either during life or after death, there was considerable overgrowth of the interstitial connective tissue or gangue, along with development of wavy fibrillar tissue, or what is histologically now known as fibroid sub-titution, or sclerosis. In the second stage the muscles were very pale, the transverse striation was either very fine, or broken, or had disappeared either in part or wholly; the longitudinal markings were very delicate, or wanting. The sarcolemma seemed to contain oil globules, which really came from the interstitial connective tissue, and were not the result of regressive degeneration of the muscular fibres, being essentially different from the changes in fatty muscular degeneration. In one of Duchenne's cases, which Dr. Lockhart Clarke examined, there were "large collections of adipose tissue between the bundles of muscular fibres." He did not remark this in the other specimens of Dr. Duchenne's collection.

To examine the muscular structure, Dr. Duchenne first soaks the specimen in a weak solution of chromic acid—the one two-hundredth. Cohnheim uses three-fourths part of a volume of concentrated hydrochloric acid in ninety per cent. of alcohol and ten per cent. of water, in which he gently boils the muscle for five or six hours.

The *pathogeny* of myo-sclerosic palsy is yet quite obscure. Duchenne writes: The formative irritation which produces the abundant nuclear proliferation and other changes in the interstitial connective tissue of the muscles, seems to be the probable cause of the paresis. But how explain the change in the connective tissue? This is still an unsolved problem. He inclines to the belief that the sympathetic system is at fault; but it does not appear that it has as yet been examined. Benedikt, remarking on the effect of the galvanic current when applied centrifugally, already alluded to, says, this single fact is a powerful reason to admit that the initial trouble is one of innervation; but he makes no attempt to localize it. It is true that the examinations that have been made of the brain and cord in this disorder have failed to show any appreciable lesion of these organs. We are, however, but yet illy prepared to positively assert the non-existence of tissue-changes in the central organs of the nervous system. We are gaining knowledge every day in this direction, and much remains to be done. The recent investigations of Charcot and others, in France, showing the connection between lesions of the anterior grey matter of the cord and nutritional tissue-errors, particularly in progressive muscular atrophy, point very decidedly to the possibility of our being able, at no distant day perhaps, to demonstrate that, in the disorder we are studying, in which the kinship is evidently near, the primary mischief is developed in some district of the gray matter of the spinal cord.

This affection is regarded by Duchenne and most of the German observers as one exclusively of childhood; but Benedikt and Grotjan report a case in a youth of twenty, who was attacked at eighteen years of age.* Duchenne indeed says that in an experience of twenty years, during which his attention has been greatly directed to this class of diseases, he has never seen any analogous disorder in the adult. In many of the cases the paretic symptoms were manifest soon after birth, and were first noticed when the child began to walk. Duchenne, Heller, and Griesinger record cases where the onset happened at five years of age, Wernich and Heller at eleven, Duchenne one at thirteen, and Heller one at sixteen. Males would seem much more liable to it than females: of Duchenne's twelve cases eleven were boys. The influence of heredity is unquestionable; Dr. Meryon reporting four cases in one family, and two cases each in two other families; Dr. Wernich mentions two brothers who suffered from it; Heller records four cases in one family; and Seidel three. Lutz tells us of two sisters, an uncle and aunt, both on the mother's side, and a daughter by the first marriage of the mother, all affected with the disease. One of Dr. Russell's cases was the third boy in a family of eight similarly affected; and another the second. The seizure in a large majority is in the midst of

* Since this lecture was in type I have read an interesting case of myo sclerosic palsy, occurring in an adult, aged 26, reported by Dr. D. Dyce Brown, of Aberdeen, in the *Edinburgh Medical Journal*, June, 1870. The man had been a gardener, and was a book-hawker at the time of his admission to the county prison; was quite healthy when he began to feel stiffish in walking, and had "like rheumatic pains" in the outside of his thighs; he complained too of pains in the lower part of the back. He continued to feel his walking difficult, and his legs were getting weak, but did not notice any muscular enlargement for about two months, when he thought his thighs began to look larger than natural. He did not sleep well, seemed heavy and stupid, but ate well, and his excretions were natural. Dr. Brown examined his thighs and found their girth increased, and the muscles felt firm, almost hard. Three weeks later the calves of the leg had become enlarged and hard. The unnatural size of both thighs and calves was now evident on casual inspection. The oblique abdominal muscles were also visibly enlarged. Two months later he began to complain of his arms feeling weaker, and that he was unable to do his task. The biceps of both arms were found enlarged, and rather firm, especially on flexion. The forearm was not increased in size, but rather the reverse, and the hands were thin and skinny, and were shut with difficulty, their grasp being very weak. When holding anything heavy, he could not help dropping it. He complained now, four months after seizure, of no pain in his thighs or legs, but of general weakness, inability to use his hands, with stiffness and difficulty of walking, which he did with a slow, waddling, side-to-side gait, and with the legs far apart. There was no pain or tenderness in any part of the spine, no anæsthesia, no headache, or other head symptoms. The skin was of normal color. The measurements of the limbs, taken six months after the onset, were:—

Girth of arm at middle of biceps, when extended,	10 inches
" " " flexed,	11¼ "
(The same in both limbs.)	
Girth of thighs opposite trochanter major,	23 "
" " at middle,	23 "
" " at lower third,	19 "
Girth of calf of right leg,	15¼ "
" " left leg,	15 "

Two months later the enlargement of the oblique abdominal muscles was more marked; the glutei began to be enlarged; and there was weakness of sight, particularly of the right eye. The muscles of the back seemed unaffected, and there was not the deep anterior spinal curvature. On ophthalmoscopic examination the state of the eyes was found as follows:—

Right eye.—S. = $\frac{1}{10}$. Retinal vessels small; pigment external to optic disc. Otherwise healthy.

Left eye.—S. = $\frac{1}{12}$. Vessels of retina small. Papillary edge of choroid showing pigment maceration. Color vision perfect.

During the time of his confinement his body-weight increased five pounds; weight on admission 157 lbs.; on discharge 162 lbs. At the time of the publication of the paper the disease was steadily progressive; there had apparently been no pause.

Jaccoud states that adult cases have occurred amongst the insane, but I have not been able to meet with any such reported.

health. In Heller's cases it seemed to follow closely on exposure to cold and dampness; in one of Duchenne's the palsy succeeded an attack of small-pox, and in another, convulsions preceded the onset. None of the subjects appear to have had rickets, except the case of Dr. T. K. Chambers to which I alluded in the beginning of this lecture.

The symptoms of the disorder, as I have endeavored to sketch them, would seem to be sufficiently distinctive to hinder any error of *diagnosis* by those who are practically acquainted with the several forms of the progressive muscular palsies in children. The physiognomy of the disease is distinct enough to secure its ready recognition. The peculiar swaying, straddling, unstable walk, the pointed toes, the deep lumbar curve, or saddleback, the pouter-pigeon chest and belly, the intent gaze, and the enlarged, hard muscles when stripped, form a picture which cannot well be misunderstood. A microscopic examination of the affected muscles should, however, always be made, and it can be readily done by an instrument devised by Dr. Duchenne in 1865, and which I here exhibit to you, and which he calls *emporte-pièce histologique* (Fig. 7). It is composed of a handle and two half-cylinders of steel, one of which is sharp-pointed with a shoulder, and the other is made to slide on the other by pushing forward a button on the handle. The fixed half-cylinder has a small cavity near its pointed end. The skin over the muscular tissue to be explored is drawn tense, and the trocar, held by the three last fingers and the thumb, the extremity of the index being so placed as to regulate the depth of the wound, is plunged open (*a*) perpendicularly into the muscle; the button is then pressed forward, which, forcing the movable half-cylinder against the shoulder (*b*), causes a small portion of muscle to be detached and caught in the cavity. The instrument is now withdrawn, the button pulled back, and the bit of suspected muscular tissue taken out for microscopical examination. The pain is slight if the little operation is adroitly done, and no ill consequences have been known to follow.

FIG. 7.

I can best and most briefly illustrate the *differential diagnosis* between progressive myo-sclerosic palsy and those affections with which it is most likely to be confounded, by these tabular statements which I have made out and condensed from Dr. Duchenne's memoir.

PROGRESSIVE FATTY MUSCULAR ATROPHY OF INFANCY.	PROGRESSIVE MYO-SCLEROSIC PARALYSIS.
1. Begins in the muscles of the face, particularly the orbicularis oris and zygomatic. After two or three years it invades the muscles of the trunk, and its course is the same as in the adult—from above downwards; affecting first the muscles of the upper extremities and of the body, and extending to those of the lower limbs later.	1. Begins, as a rule, in the lower limbs, whose muscular power is weakened; its course is from below upwards, the upper extremities and the muscles of the trunk becoming involved after a considerable interval of time.
2. The muscles atrophy partially and irregularly, one after another; muscular debility in a limb is not general, but limited to the affected muscle or muscles, and is in direct proportion to the degree of atrophy; the consequence of which is, the several partial muscular paralyses and the various deformities in the muscles of the trunk.	2. Muscular weakness from the outset affects a large body of muscles, connected with several joints; later some of the paretic muscles, and more rarely all of them, become apparently hypertrophied.
3. The muscular fibre undergoes granular or fatty degeneration, and interstitial fatty substitution.	3. The muscular interstitial tissue shows a remarkable proliferation of the elements of connective tissue, with abundant production of fibroid tissue, and more or less fat globules. Some striation of muscular fibre often exists.
4. Muscular motility is not abolished until after the tissue changes.	4. Muscular motility is lessened or abolished.

FATTY ATROPHIC PARALYSIS OF INFANCY.	PROGRESSIVE MYO-SCLEROSIC PARALYSIS.
1. Begins in a large majority of cases with febrile symptoms.	1. Apyrexia throughout the course of the disorder.
2. May be generalized, paraplegic, bilateral, or crossed, limited to one limb, or a portion of a limb at the outset. When all the muscles are completely paralyzed from the outset, those whose innervation is the least damaged soon recover their power, whilst the others become greatly atrophied, or their texture is changed in different degrees.	2. At the outset, paresis affects the muscles of the lower limbs and the extensors of the spine, and their power is weakened. At a later period the power of motion is totally lost.
3. In the first stage electro-muscular contractility is lessened or absent, although there may be no muscular tissue-change.	3. In the first stage electro-muscular contractility unimpaired (this is doubtful, and requires further observation to confirm it).
4. At an advanced stage the loss of motility is soon followed by atrophy, more or less rapid and complete, according to the degree of the nervous lesion.	4. Paresis is soon succeeded by a considerable increase in the size of a greater or less number of muscles.
5. At an advanced period the loss of voluntary and electro-muscular contractility, shows that the muscles, whose innervation has been damaged, have undergone serious tissue-changes.	5. In the third stage of this disorder, if the enlargement of the muscles has disappeared and the limbs seem atrophied, a microscopic examination of a portion of an affected muscle taken from the patient, shows that the primitive fibres have, generally, preserved their transverse striation, and that the proliferated connective tissue is mingled with fibroid substitution and fatty vesicles, in greater or less quantity.

With respect to *prognosis*, of immediate danger in the early stages of the disorder there is little risk. In most instances the course is a regular one, the patient dying in from two to five years from an acute intercurrent disease or from exhaustion. In some cases the duration is much longer. M. Duchenne's early cases all perished in this way; but recently he states that he has twice arrested the disease in the early stage, and the cure seemed permanent. He argues that if it were more frequently detected and treated at the outset, which, from the early paretic symptoms escaping notice on account of their slightness, but rarely happens, the prognosis might become quite favorable. This is probable, because at this stage the myo-sclerosic change and the centric lesion on which it depends, are most likely but little advanced. When the disease has once become generalized, the patient is surely condemned to incurable infirmity and early death. In Benedikt's case, however, the young man of twenty, I should mention that though the affection was of two years' duration, and most of the muscles of both extremities had the characteristic false hypertrophy, still, after treatment by galvanism, he improved so much as to be able to resume his trade of tinman.

And this naturally leads me in conclusion to speak of the *treatment*. Duchenne uses faradism localized, shampooing of the damaged muscles, and hydrotherapy. In the second stage these means proved only temporarily relieving, the disease resuming its course and going on to a fatal ending. He tried also ergot, strychnia, and iodide of potassium unsuccessfully.

Let me urge you in this, as in all chronic diseases of the nervous system involving nutritional changes, to put your trust rather in those means, regimenal and other, which improve the general health, and look upon all others as auxiliary. Give arsenic

in very minute doses for a long time, and short periods of rest, with the phosphates, and cod-liver oil; insist on nourishing food; and baths and hand-rubbing of the whole body. The paralyzed muscles should be electrized for five minutes at a time, three or four times a week. The constant current of low tension should be used in connection with faradism. It is possible that galvanization of the sympathetic may prove of service; at all events the trial is worth making.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

Article III.

FLEXION AND EXTENSION, HOW DETERMINED—"LONG" AND "SHORT" MUSCLES—TELEOLOGICAL VARIATION—MUSCLES OF SHOULDER AND HIP.

From what has preceded, and especially from the law enunciated, it is evident that corresponding muscles are to be sought upon antitypically correlated aspects of the limbs, and determined mainly by position and relation. Their size and shape are as nothing, and their function is a matter of only secondary consequence. For the same muscle may be developed in inverse ratio in different animals; a flexor may even become an extensor, and conversely, by slight variation in its attachments and line of traction.

Antitypically correlated are opposed sides of the limbs in longitudinal direction; and the same sides in transverse direction. Thus the front of the arm corresponds to the back of the thigh, the back of the forearm to the front of the leg, and conversely, etc. The outside (radial aspect) of the forearm corresponds to the outside (peroneal aspect) of the leg, etc.

In this investigation it becomes necessary to change certain obvious misnomers that anthropotomists have imposed upon muscles of the forearm. The so-called "extensors" of the wrist are really *flexors;* the so-called "flexors" are really *extensors.* This is demonstrable. Remembering the position* of the body already determined, the shoulder points forward, the hip backward. Then, "flexion" or bending of the humerus is the bringing of that bone in the opposite direction from that of the preceding segment (scapula), *i. e., backward;* flexion of the forearm is bending that segment in the opposite direction again, *i. e.*, forward. So, of course, "flexion" of the carpo-metacarp is bringing that segment once more in opposite direction, *i. e., backward.* Now the muscles that effect this lie upon the back of the forearm; they are those called extensors, but are obviously flexors.† The reader will, therefore, bear in mind that in speaking of wrist-muscles, my "*flexors*" are his "extensors," and conversely. No change is required in cases of the muscles that act upon the tarso-metatarse; that their actions have been correctly designated, is evident from the fact, that extensors come down upon the back, and flexors upon the front, of the leg, and are thus antitypically correlated with those of, respectively, the front and back of the forearm, after the required change in these last has been made.

Professor Wilder has determined and applied certain principles in respect of the attachments and action of muscles that are of some importance in the identification of homologies. This is the substance of what he says;* I would quote in full, were space less an object:—Each segment of a limb is primarily bent by two muscles or sets of muscles, the 'long' and 'short' flexors; is also straightened by opposing 'long' and 'short' extensors. Of both of these, the 'short' reaches over only two contiguous segments—from the segment of origin to the immediately succeeding segment of insertion; it can consequently act in but one way, *i. e.*, to produce simple flexion or extension. The 'long' flexor or extensor, on the other hand, reaches over three segments, arising from the next segment but one above the segment to be moved; besides primarily or 'directly' acting upon the latter, it secondarily or 'indirectly' acts upon its segment of origin to produce motion in the contrary direction. Thus a 'long' direct flexor of the forearm is an indirect extensor of the humerus. *Illustrations:—Brachialis anticus* is a short direct flexor cubiti; it only bends the elbow. *Biceps* is a long direct flexor cubiti; and is extensor humeri as well. *Gastrocnemii* are long direct extensores tarsi; indirect flexores cruris, from their femoral origins; etc. etc. Besides these primary groups there are others called 'accessory,' as will appear in the sequel. The manifold advantages of such an arrangement will be evident upon the close study that the importance of the subject warrants. I introduce it, however, not to show the advantages in question; but simply for the bearing that the general principle involved may have in some disputed cases of homology. Yet we must not lean upon it too heavily; had the author himself laid less stress here, some of his special determinations might have been differently made.

Morphologically speaking of the movements of limbs, all these may be reduced to flexion and extension. Adduction and abduction are evidently these motions in transverse instead of longitudinal direction. 'Circumduction' is a compound of the two, with one end of a segment fixed, the other swinging: 'rotation' is circumduction with a stationary axis.†

We must never lose sight of the fact, that muscles are constantly specialized in each group of animals, to enable them to accomplish the particular actions de-

* Horizontal, limbs dependent, slightly bent at each joint; forearm supine, palm downward and forward, fingers pointing backward, nails uppermost.

† "Flexion" of course means only *bending*, and extension *straightening;* a bent limb is shortened, and a straight one is therefore "extended." Morphologists give more definite meanings. Flexion with them is bending a segment in a direction opposite to that of the preceding segment; extension is the decrease of this bending to *nil*, or the carrying of it beyond a straight line. When, therefore, as happens in the forearm when this is bent at the elbow, and the hand further brought round toward the *front* of the forearm, and the fingers closed, *three* segments *appear to be* bent in the same direction; an extension (of the wrist) has really intervened: *q. e. d.*

* B. G. Wilder, "*On Morphology and Teleology, especially in the Limbs of Mammalia.*" Mem. Bost. Soc. Nat. Hist., I. (Nov., 1865).

† In the movement called *pronation* may be discerned the elements of all possible motion of limbs. To explain: Drop the left arm perpendicularly, with forearm supine, palm forward, thumb outside. Now pronation of the hand through the first quadrant (90°) of a circle is *adduction* of the thumb; further pronation is *extension*, the thumb being carried backward, with reference to the whole body. So far, we have had *circumduction*, through 180°. If now further pronation were possible, the next or third quadrant of the circle of circumduction would be *abduction* (carrying of thumb away from axis of body); and the fourth and last quadrant would be *flexion* (bringing the thumb forward with reference to the whole body). This would complete the circumducting circle, as when a whole arm swings in a circle and describes a *cone:* the thumb has regained its original position. In this, the forearm has been a right-angled triangle, with radius for hypothenuse, ulna for perpendicular, and diameter of wrist for base; it has generated a cone by revolution about its perpendicular. Now let the base be reduced to zero, and the above movements resolve into simple *rotation*, like that of head of the radius in the lesser sigmoid cavity. Such is the essential correlation of all movements of limbs as wholes, or of their individual segments similarly regarded.

signed. This specialization obscures morphology in different ways. It may add to, or subtract from, a given species, whole muscles or even groups of muscles; it almost always modifies size, shape, and function; *e. g.*, man has muscles that all other animals want, and wants some that most other animals have. Muscles may slide up and down a limb, as to their attachments (less frequently as to insertion than origin). Besides being thus dislocated, muscles may be dismembered, and appear as two when they are a morphological integer; and conversely; of both of which modifications man affords some signal instances. The detection of homologous muscles in different animals, even, say, of the mammalian series alone, is sometimes impossible, often very difficult; the attempt is always to be cautiously made. So, regarding muscles of the two extremities of the same animal (which are ideally identical) we cannot hope to trace unquestionable homologues all the way through. We shall do well, if we determine so many, that failure to identify the rest may fairly be attributed rather to defective vision of ours than to want of whereupon to exercise it. And if even one muscular homotype be determined beyond shadow of doubt, it would serve to uphold the doctrine we advocate. One such is demonstrable: the theorem involved may be thus enunciated:—

The humerus and femur being in a certain sense correlated, the triceps humeralis *and the* triceps femoralis *are in the same sense correlated.*

The foregoing appear to be the principal *præmonenda* required at this stage of the discussion.

The scapular arch of man is attached to the head and trunk by the sterno-clavicular articulation and nine muscles, viz.:—(1) pectoralis minor, (2) subclavius, (3) cleido-mastoideus, (4) omo-hyoideus, (5) levator anguli scapulæ, (6) serratus magnus, (7) trapezius, (8 and 9) rhomboidei. Both in number and distribution these are under special not general conditions, in provision for the unusual freedom of movement of the fore limb. Nos. (8 and 9) are clearly the same muscle; even in man the *rhomboideus minor* may be "wanting," or merged in the *rh. major;* in many animals there is never but one, forming a great plane underlying the trapezius from occiput downward. Comparative anatomy also shows that Nos. (5) and (6) are one morphological integer. Thus I find in a low marsupial (but one with muscles surprisingly human-like) that these form one continuous, broad, fan-shaped plane, extending unbroken from atlas to last 'true' rib, and thus over the whole side of the thorax as well as of the neck; arising by digitations from all the cervical ("transverse processes—posterior tubercles") and most of the dorsal ("ribs") pleurapophyses, converging to connect these with the apex of the narrow transverse scapula. A further reduction of the seven thus remaining is probably to be made, in the case of the pectoralis minor. This only goes from thorax to coracoid in higher mammals; in lower, it may be wanting, unless represented in one of the several subdivisions of the great pectoral, all of which go to the next segment (humerus); in birds, with three perfectly distinct pectorals, there is no such costo-coracoid connection; all the pectorals act upon the arm, not the scapular arch. On the other hand, the cleido-mastoideus, in man an offset of the sterno-cleido-mastoid, is a distinct muscle in brutes, when existing; and lower animals generally have one or more additional and very distinct lifters of the scapula towards the head, often resembling our omohyoid, but arising from the vertebral column.

Those hold a reasonable view, who refer the six or seven muscles above mentioned to those of the trunk rather than of the anterior extremity. When we remember that the shoulder-arch has virtually or potentially slipped from its morphological position at the occiput, to the thorax, we reason with our host in anticipating that it would retain at least muscular connection with the vertebra to which it appertains. Its muscles appear to belong to the intercostal or other of the vertebral series. Some of them bear out this view in a striking manner. Thus the subclavius is actually a pure intercostal; it is the interc. internus between the first rib and the clavicle. The omo-hyoid is an instructive example in point. It precisely and directly connects the corresponding parts of two contiguous cranial vertebræ (—hyoid bone and scapula; hæmal arches of, respectively, mes- and ep-encephalic vertebræ), and has no other discoverable *raison d'être;* it cannot work upon the shoulder to any notable extent, compared with the scapular muscles proper; its consentaneous action with its fellow does nothing that other hyoidean muscles do not, and there is no occasion for the hyoid to be forced to either side. And in some animals, as above stated, the scapula is further hung from the head by one or more ribbons that arise from certain processes of the atlas, and pass to acromion, or upper border of scapula. Cleido-mastoideus is cranial; so is trapezius; in many animals the rhomboideus is also. While the morphology of the muscles of the shoulder-girdle probably remains to be proven, the evidence in favor of the view here taken is weighty; and at present we certainly have no more reasonable conclusion at our disposal, than to consider them as trunk-muscles specialized for a particular purpose, according to a law that has eluded our grasp.

Although it is not proper to take any element of a conclusion we desire to reach as a premise in an argument, yet some might consider the condition of the proximate segment of the hind limb as affording corroborative testimony in the above case. However this may be, it is certain that muscles corresponding to these of the scapular arch do not exist in the pelvic. The latter is firmly and immovably attached to the spine by the sacro-iliac synchondrosis and one* muscle —*psoas parvus.* This is an inconsiderable muscle in man, inconstant, occasionally wanting on one or both sides; but in other mammals it may be larger, etc., than the one called *psoas magnus* that goes to the femur; and it is by no means to be ignored. It arises from the vertebral centra at junction of dorsal and lumbar series, and is inserted into the linea ilio-pectinea. There is nothing that it obviously corresponds to in the forelimb; nor could there be, owing to the conformation of the thorax. Its morphology is uncertain; though perhaps determinable, it still remains indeterminate.

There are six small muscles about the head of the thigh-bone, collectively known as "rotatores femoris." Of these, the "twins"—*gemellus superior et inferior*—are of course dependencies of the obturator upon the tendon of which they are situate; leaving four —*pyriformis*, two *obturatores* and *quadratus femoris.* There is good reason to doubt that these are all morphological integers. The quadratus, especially,

* Without taking into consideration, of course, the several abdominal and dorsal muscles that certainly belong to the trunk, and are only incidentally attached to the pelvis. The fact of there being here such unquestionably trunkal muscles is the one just alluded to as that strengthening the hypothesis that the various muscles of the scapular arch are really vertebral, teleologically specialized and devoted to the movements of the fore limb. The psoas parvus I suppose to be hidden among these latter. Similarly, genito-urinary and other muscles that arise directly from the pelvis, do not belong to that arch with reference to the limb that hangs from it; if they have any anterior homotypes, these are certain head-muscles; as sphincter ani=orbicularis oris, etc. Again, in tailed quadrupeds, caudal muscles arise from the pelvis or even the leg; these of course continue the trunkal series.

seems less one of this set, than a part of the adductorial group upon the inside of the thigh; it is an almost direct upward continuation of the adductor magnus. The three remaining muscles represent a 'long' (pyriformis) and two 'short' ones (obturatores) that are special additions to the posterior extremity, and have no correlatives, as far as known or even surmised, in the anterior. The proximal extremity of the humerus is, without calling in the aid of muscles corresponding to these, already perfectly supplied with rotators. They may indeed be ideally enwrapped in some of the scapulo-humeral muscles; but this is a supposition not colored by anything, so far as I know, that has yet been adduced. The *teres minor*, if really an integer, might answer for one or some of them; but such identification would be purely presumptive. The great development of the ischiatic hæmapophysis, compared with the rudimentary condition of the anterior one (coracoid), probably has something to do with the matter, and renders it unlikely that there should be anterior correlatives of the quadratus and obturatores; and from the conformation of the thorax, there is no way of escape for a muscle arising from dorsal centra, as the pyriformis does from sacral. In short, it may be said that identification of the *rotatores femoris* is not to be made at present.

In such difficulty in respect of the first muscles of the thigh encountered, we may as well next take up that one of the anterior extremity that offers the chief if not the only other obstacle, among the muscles acting upon proximal extremities of the humerus and femur. I refer to the largest and one of the most important muscles of the fore-limb—the *latissimus dorsi*. Anatomists differ in their views of its homotypy; while it almost certainly has some posterior correlative, yet this cannot be said to have been fixed. Wilder queries the muscle, without attempting to suggest a correspondent; "it seems," he says, "to have no posterior correlative" (*loc. cit.*, p. 31). It is to be observed in the first place, that this muscle is the long direct flexor of the humerus; for it draws that bone backward, and has vertebral origin, skipping the scapula, and thus arising from what is virtually the next segment but one above that acted upon. It also rotates the humerus so as to throw the elbow outwards. One of the femoral muscles executes the counterpart of these actions. The *psoas magnus* flexes the thigh, *i.e.*, anteduces it, and moreover so rotates it as to throw the knee outwards; it is likewise the 'long direct' flexor, arising from vertebræ, and skipping the ilium. The two muscles, besides being identical in these respects, are 'symmetrically disposed' in general direction; which is forward, outward, and downward in the one case; backward, outward, and downward in the other. There are, however, two serious objections to this identification. In the first place, the *psoas magnus* may be morphologically identical with the iliacus. Although the two are perfectly distinct in man and some other animals, or have at most a common trochanteric insertion, yet in others again they are to the physical eye the same, being extensively blended, having not very dissimilar origin, and identical insertion. The point remains open. The other is more serious, and is, I believe, the main difficulty. *Latissimus* is superficial, dorsad of vertebral centra, with origin from vertebral spines: *psoas** is profound, ventrad of vertebral centra, and arises therefrom. But no other identification of latissimus seems probable, whatever view be taken of the relations of the psoas to the iliacus. I rest for the present upon the above presumptive evidence.

If we have not yet arrived at anything as satisfactory as could be desired, it must be remembered that at the outset difficulties are more numerous and formidable than elsewhere, in strict accordance with the principle already laid down, that specialization involves obscurity in direct ratio. At the shoulder and hip we have inverse muscular development, in provision for the diametrically opposed conditions of mobility and stability. We shall find that the way grows smoother as we advance upon the limbs from these points of departure.

* Prof. Wilder's reference (*loc. cit.*, table on p. 32) of the psoas magnus to the *supra-spinatus* is certainly a mistake, for it is not an "accessory short extensor" femoris, as implied in such identification, but the reverse. My esteemed correspondent himself corrects the error which is seen by the following extract from a letter received, to be merely an inadvertent misprint. " * * Your question shows me an error that I never saw before. Psoas magnus and glutæus medius should change places in the table, according to the statement upon the preceding page." This change brings psoas magnus opposite *infra-spinatus*, as accessory short flexor femoris; regarding which view, see my next paper.

LIGATION OF ART. ILIAC. EXTERN. FOR FEMORAL ANEURISM,

A YEAR AFTER A SIMILAR OPERATION ON THE RIGHT SIDE.

DEATH FROM SECONDARY HEMORRHAGE ON TWENTIETH DAY.

By C. C. TERRY, M.D.,

NEW YORK,

Being the report of a specimen presented to the N. Y. Pathological Society, June 8, 1870.

J. H. Hatton, about thirty years of age, was successfully treated for right femoral aneurism by ligation of the external iliac art. in January, 1869. The ligature came away on the twenty-third day, and he was about in two months. The temperature of the limb was not perceptibly affected by the operation.

Soon after commencing to go about, he observed a painful swelling in the left groin, which, gradually increasing in size and inconvenience, was presently recognized as an aneurism of the left femoral.

When examined in May, 1870, there was a pulsating, elastic tumor, the size of an egg, tapering upward under the crural arch and downward in Scarpa's space. No bruit heard. Pressure upon this fusiform tumor diminished its size, and the force of the pulsation in the distal vessels; but increased the tension in the aneurismal wall, and the pains of which he constantly complained in the loin and down the limb. The success of the former operation enabled him to anticipate another with great cheerfulness; but, before making the ligation, we decided to invite Dr. Guleke to try electrolysis in the sac.

May 13, 2 P.M. Right popliteal space, 98° F.; left popl., 96°; axilla, 98¼°; pulse, 72 (excited); respirations, 24. His normal pulse is 60–65.

2.10 P.M. Chloroform.

2.20. Anæsthesia; right popliteal, 98°; left popliteal, 95½°; axilla, 98½°; pulse, 68.

2.32. Right popl., 98°; left popl., 95½°; axilla, 98½°; pulse, 68; positive needle thrust into anterior aspect of aneurismal tumor, negative pole applied to surface of opposite thigh. The test-decomposition had been readily produced the instant before closing the current.

2.45. Left popl., 94°, needle withdrawn. Tumor smaller, firmer, less elastic; pulsation less heaving. Pulsation feebler in popliteal and tibial arteries, and limb tangibly cooler. Several drops of red blood followed the withdrawal of the needle.

2.50. Needle reintroduced at another point and kept in ten minutes.

9 P.M. No perceptible change in the tumor, but more pulsation in the distal vessels and limb—warmer; right popl., 98°; left popl. 98°; axilla, 98½°.

May 14. A singular effect of the needle has been the almost abolition of the former lumbar and crural pain, so that now he speaks only of an occasional sharp pain in the groin.

May 15. Pulsation of distal vessels as before operation, but the aneurismal tumor still somewhat smaller and harder than before the use of the needle.

May 16. Positive needle reintroduced at a new place; the negative pole being applied on the opposite thigh. After thirty-nine minutes, during which the struggling and groaning, even while anæsthesia of the conjunctivæ was marked, indicated much suffering, nothing was accomplished beyond a zone of redness around the needle, and several small blisters where the negative pole had rested, and the external iliac was ligated just below where crossed by the circumflex veins. Pulsation beyond the ligature ceased at once. Some hours afterward a slight fluctuation could be felt in the sac; but no distinct pulsation recurred in the distal vessels, nor was the temperature at any time notably affected.

The wound commenced discharging, on the fourth day, a small quantity of opaque fluid; it was dressed with a solution of carbolic acid; the sac shrank but little, yet became harder; and everything seemed going on to our satisfaction, until a slight oozing of dark blood appeared at the wound on the fourteenth day. Next day Dr. Guleke saw him in my absence, and considered the hemorrhage superficial and trivial. Ice was applied, and the patient kept as still as his uneasy disposition would permit, but the bleeding recurred in small quantities occasionally, mixed with the discharge, until a considerable bleeding on the nineteenth was followed by a sudden and fatal hemorrhage on the twentieth day.

Secondary ligations in the iliac region have discouraged many surgeons. In this case there was suspicion of atheroma, and Dr. Hamilton had advised that it was quite as well for the patient to take the certainty of the present hemorrhage as to wait a few days longer for another. Still one feels a natural desire to improve even the smallest chance of success, and after the bleeding of the nineteenth day had been checked, I was ready to religate at the first warning.

Sectio cadaveris four hours after death. Surface and mucous tissues pale. From the wound extruded a gelatinous mass of blood-coagulum continuous with a mass which lay upon the divided vessel, and had distended the meshes of the sub-peritoneal connective tissue into a large cavity.

The ligature had cut clean through the vessel, leaving two gaping mouths. Below, the vessel was pervious to the sac; above, its lumen was partially occluded by a worm-like fibrinous cord, which commenced at the giving off of the internal iliac, and clung to the wall of the external down to near the place of ligation.

The divided extremities of the vessel had retracted and been pushed asunder, so that their open mouths lay nearly a finger's breadth apart. Many atheromatous patches were visible in the walls of the vessel, both above and below the ligation.

The sac was two-thirds filled by a pretty firm, striated coagulum adherent to the anterior and lateral walls. In the anterior wall a small eschar was being formed at the site of the last needle-puncture.

The walls of the sac were thin; the superficial femoral vessels obliterated; the profunda branch as large as the femoral above it.

The nerve on one side and the vein on the other were intimately adherent to the sac, which itself was abnormally adherent to the posterior wall of the crural canal. After the severance of the vessel by the ligature some blood may have reflowed from the sac to the wound—most directly from above. How much the internal epigastric contributed by its anastomosis with the mammary, the unavoidable haste of the autopsy prevented my ascertaining. At all events, the vessel was quite large.

On the right side the cutaneous cicatrix sent down a thin plane of cicatricial tissue which reached the pelvic aponeurosis, thickening to include the ligated portion of the external iliac just below the internal iliac. Thence down to the flattened fibrous mass which represented the former right aneurismal sac, the vessel was a small impervious cord. The femoral became pervious just below the sac, and immediately gave off a profunda branch larger than itself. The vein adhered closely to the sac; the nerve was loosely attached.

For neither aneurism was there any history of traumatism. Possibly atheroma was the principal factor of both, of the fatal result.

Progress of Medical Science.

CONTRA-INDICATIONS TO THE EMPLOYMENT OF CHLORAL.—The late Dr. J. Y. Simpson (*Medical Times and Gazette*), in his "Therapeutic Notes on Chloral," remarked as follows: "I am not aware of any special contra-indications to the employment of chloral when used for somniferous purposes. Even in head and chest affections, when I should have been chary of having recourse to opium as an hypnotic, I have employed chloral with perfect success. The contra-indications to opium offered by a tendency to constipation, etc., do not exist against chloral."

THE REMOVAL OF CYSTIC TUMORS FROM THE EYELIDS.—Julien J. Chisolm, M.D., Prof. of Op. Surgery, and Clin. Prof. of Eye and Ear Diseases in the University of Maryland (*The Baltimore Med. Jour.*), describes his modification in the use of the nitrate of silver that he has found so effective in the treatment of sebaceous cysts of the lid, and which has enabled him to discard for many years the tedious, painful, and sometimes dangerous cutting out of such tumors. If the tumor be a sebaceous cyst, located between the upper portion of the tarsal cartilage and the skin, a Desmarres ring forceps is used as a clamp upon the lid, to shield the ball of the eye from injury, to fix the tumor, and prevent annoying oozing of blood. Under this ring pressure a small opening is made into the cyst, through which its contents are squeezed out. The end of a small silver probe dipped in nitric acid, is then passed into the cavity, is made to pass over the epithelial lining surface, and is withdrawn. Usually, in its passage into the cavity of the tumor, it cauterizes sufficiently the lips of the incision to prevent any oozing of blood when the clamp forceps is removed. When the cyst is formed by the closure of a meibomian duct, the better plan is to evert the lid and make the puncture from the conjunctival surface, the caustic being applied as directed. The advantage gained by this modification is in the more certain, thorough, and yet restricted application of the caustic, confining its cauterizing influences only to those

portions in which action is desired. The results are in every case satisfactory—no after-treatment is needed.

THE CAUSE OF SUMMER CHOLERA.—C. F. Buckley, M.D., of San Francisco, Cal. (*California Medical Gazette*), in a recent paper before the San Francisco Medical Society, after dividing simple diarrhœa into six different varieties, adds a seventh, viz.: Summer Cholera. He rejects the idea that fruit is the general cause of summer cholera, and is inclined to think it is due to an undue elevation of temperature; he also believes the affection is merely a modification, in a milder degree, of insolation or sunstroke. With undue elevation of temperature in the first place, the branches of the hepatic artery become expanded, causing more or less obstruction to the portal circulation; secondly, the smaller branches of the mesenteric arteries enlarge, causing more or less obstruction in the villous circulation. It is quite clear that a continuation of both causes will produce very extensive congestion of the intestinal capillary circulation, and so leads ultimately to diarrhœa.

In concluding, he advocates the "castor-oil treatment," which, in Asiatic cholera, yielded more favorable results in the vast majority of cases, in the institution with which he was connected, than any other remedy. The castor-oil should be combined with mucilage and chloric ether.

He has never tried cooling draughts, but intends to do so at the earliest opportunity.

THE FORMATION OF FUNGI IN DIPHTHERIA.—According to Hüter (Virchow's Archive), Letzerich has proved that the commencement of diphtheria is a putrid state of the tissues through the formation of a low grade of fungi.

FORCED FLEXION AS A MEANS OF ARRESTING ARTERIAL HEMORRHAGE.—Dr. G. Adelmann, Professor of Surgery in Dorpat, recently published nine cases occurring in the extremities, in which forced flexion was adopted, and the hemorrhage arrested without ligation. To insure forced flexion, a plaster-of-Paris bandage is preferable in a long transportation.

THE THERAPEUTIC USES OF CHLORAL.—M. M. Pallen, M.D. St. Louis, Mo. (*The St. Louis Med. and Surg. Journal*), coincides with M. Demarquay that Dr. Liebreich's assertion "that chloral is decomposed in the blood, and that the chloroform resulting from this decomposition produces anæsthesia," is not the correct view. If chloral acts as an hypnotic and as a hyperæsthetic, it cannot be *totally* converted into chloroform. There is no doubt in his mind that chloroform is produced during the action of the chloral, but the chloroform arises chiefly by oxidation in the lungs. Dr. P. coincides with those who think that it is an hypnotic, and valuable as such an agent where opium cannot be used. He has used it extensively in monomania, endometritis, and puerperal convulsions, to procure sleep; in some instances in doses as high as a drachm; to children in doses from six to twenty grains, according to age.

It is applicable in that form of affection known as night-terrors. The child is sleepless, or even when it sleeps the slumber is disturbed, and it moans or it grits the teeth. All this should be overcome, or else the child in after years will be an epileptic. Chloral is the remedy, opium the poison. The dose to children will vary from four to twelve or more grains. He always uses, as the vehicle with which to mix the chloral, the syrup of tolu.

SYPHILITIC HEADACHE.—Dr. Edward H. M'Clean, Lyndhurst (*Lancet*), finds that the simple headache met with almost daily, in ordinary practice, is one of the sequelæ of syphilis. For this headache we have in the iodide of potassium a remedy which is a veritable specific. This remedy, in five-grain doses, three times daily, will ordinarily cause the trouble to disappear within a few days.

THE GERM THEORY.—Prof. Tyndall, LL.D., F.R.S., the great advocater of the "germ theory" of the propagation of disease, asserts that in this way the Asiatic cholera, from a small beginning in the delta of the Ganges, in seventeen years occupied nearly the whole world.

COLLODION IN INCONTINENCE OF URINE IN CHILDHOOD AND YOUTH.—Sir D. J. Corrigan, Bart., Phys. in Ordinary to the Queen in Ireland (*Dublin Quar. Jour. Med. Science*), recommends the application of collodion as the best mechanical treatment of incontinence of urine during sleep, in childhood and youth. It is most easy of application, occupies scarcely a minute, and can be carried out at school, college, or elsewhere, in perfect privacy.

All that is necessary is, while the prepuce, slightly curved up, is held with the left hand, to smear over the little cup thus formed by the extremity of the prepuce with collodion by means of a small camel's hair pencil or blunt end of a penholder. The collodion solidifies almost as fast as applied. In contracting it draws closely together the edges of the prepuce, and thus the exit for the escaping urine is closed.

TYPHOID FEVER CONTAGIOUS.—G. E. Frothingham, M.D. (*Mich. Univ. Med. Journal*), publishes twelve cases of typhoid fever, out of ninety cases, referable to contagion.

He coincides with the assertion of Prof. Austin Flint, "that as a rule people have this disease but once."

Care should be observed in the disposal of the alvine evacuations, which there is reason to believe are particularly active in the contagious properties. These should never be thrown into the common privy, and their contagious principle should be at once destroyed by the use of antiseptic agents. All the clothes used about the patient should, upon removal, be rinsed thoroughly in a solution of chloride of lime of proper strength, before they are washed. Dr. Wm. Budd regards a solution of green copperas, of the strength of a pound and a half of the salt to a gallon of water, the best that can be used.

PERMANGANATE OF POTASSA IN OXALURIA.—Dr. H. S. Thorne, of Chicago (*Mich. Univ. Med. Journal*), gave the subjoined prescription to a man, æt. 45, afflicted with dyspepsia and oxaluria: Permanganate of potassa in grain doses, to be made into pills with bread, three to be taken per day for ten days. A few days afterward he returned and stated that he was cured. On examination of his urine not a crystal of oxalate of lime could be seen. The symptoms, including the dyspepsia, disappeared.

Dr. Rose, of the Michigan University, had previously prescribed it in one case, in the following form:—

℞ Permanganate of potassa, gr. viij.
Aqua, ℥ ij.

M. Sig. One teaspoonful to be given three times a day.

It should not be given except on an empty stomach; for in contact with organic matter it is decomposed, yielding its oxygen to any element, simple or compound, that will receive it.

TURPETH MINERAL IN CROUP.—Prof. Fordyce Barker, M.D. (*Am. Jour. of Obstetrics*), always commences the treatment of croup by an emetic of turpeth mineral

(hydrargyri sulphas flava), in doses of from three to five grains, according to the age of the child. If it does not act in fifteen minutes, he directs a second powder to be given. This, however, is rarely necessary. His reasons for preferring this to all other remedies in croup are the following: It acts much more promptly and efficiently than ipecac or alum; it is tasteless, and much more easily administered than either; it does not exhaust and depress the vital power like antimony. It is equally prompt in its action with the sulphate of copper, while it is much more effective as a revulsive and sedative. This emetic should be given immediately on the appearance of the symptoms which threaten croup. It is the only medicine which he has constantly carried in his pocket for twenty-eight years. In all families with young children that he attends, when the slightest tendency to catarrhal laryngitis has been manifested, he has been in the habit of directing that this medicine should be constantly kept where it can be readily found; and he has no doubt that at this moment a hundred families in this city have three-grain powders of the turpeth mineral carefully labelled "croup-powders." There is one advantage in their use which must not be omitted; if the supposed attack of croup is simply one of laryngismus stridulus, or of what is called false or spasmodic croup, the powders do no harm.

It has sometimes occurred that he has found evidence of increasing laryngeal and tracheal obstruction, and has in consequence repeated the emetic of the turpeth mineral on the second or third day; but he has never had occasion or deemed it well to repeat it a third time.

The Use of Quinine in the Diseases of Childhood.—C. Bing, M.D., Professor of Pharmacology in the University of Bonn, Germany (*Am. Jour. of Obs.*), regards quinine as an important remedy in those diseases of childhood thought to be dependent on septic or zymotic conditions, like measles, scarlatina, and diphtheria. In scarlet fever, quinine should be given from the *very commencement* in sufficiently large doses, the progress of the disease carefully watched by the aid of the thermometer, and the doses increased in quantity if the fever grows threatening.

Of the acute exanthemata of infants, he would mention one particularly as being within the sphere of the influence of quinia, namely, *erysipelas neonatorum*. As a general rule, an internal dyscrasia, or an external putrid ulceration of the navel, is assumed as the cause of this fatal disease.

The action of quinine in this disease is attributed to the overcoming of the alteration of the blood, to the diminution of the high temperature, and to the direct removal of the histological causes producing the erysipelas.

In pertussis, quinine has answered his expectations. Three conditions are absolutely necessary if we desire any good results from it in whooping-cough. It should be given in solution; the dose should not be too small, and should not be administered in a vehicle that will prevent it from coming in contact with the mucous membrane in its passage through the pharynx. The preparation should only be given when dissolved in muriatic acid, unless we are desirous of employing the alkaloid combined with that acid. Its constantly increasing price is a great obstacle which the physician often encounters in prescribing quinine extensively. This may be avoided by resorting to the amorphous chinine-chinoidine; and Prof. Bing states, in closing, that the preparation lately introduced into commerce by C. Zimmer, of Frankfort-on-the-Main, under the name of chininum muriaticum amorphum, cannot be too highly recommended.

Veratrum Viride in Dysentery.—Dr. A. M. Ragland, Shelbyville, Texas (*The Med. Archives*), advocates veratrum viride in dysentery, and alludes to a case of a boy, æt. 6, who, when first seen, had from 30 to 40 evacuations in 24 hours; pulse rapid, small, and wiry, numbering 130 per minute, and the temperature, as indicated by the thermometer in the axilla, 103.5 F. Wishing to reduce the too rapid action of the heart, he gave veratrum viride, commencing with three drops of Norwood's tincture, and increasing one drop each dose, which in six hours brought the pulse from 135 to 60 or 70 beats, and in corresponding ratio the temperature was found to have fallen to 101° F.

The marked benefit of the treatment was shortly manifest in the lessened number of evacuations and reappearance in them of fæcal matter. The child made a good recovery, convalescing steadily from the time of the favorable change.

Did the veratrum's remedial influence act directly upon the disease-process, arresting the molecular disintegration which was going on, and the development and elimination of preternatural heat, by controlling the destructive metamorphoses caused by the action of the disease poison upon the tissues?

Bony Anchylosis of the Elbow-Joint.—Dr. Louis Bauer, St. Louis, Mo. (*St. Louis Med. and Surg. Journal*), first describes a case of "Total Exsection of the Elbow-joint," and remarks:—Some eminent surgeons have recommended and performed the exsection of the elbow in bony anchylosis as a legitimate operation, for no other object than to restore the lost mobility to the articulation. He is not able to strengthen their case by his assent; the results of three operations for the specified purpose of removing carious bone do not encourage the hope of a very useful arm. Unless the position was very awkward and disfiguring, he would be disinclined to consider bony anchylosis of the elbow-joint a sufficient indication for operative interference.

A Case of Fracture of Portion of the Cranium—Recovery.—Dr. A. A. Shutt, Springfield, Mo. (*Med. Archives*), publishes the following case of fracture of cranium:—A negro boy, æt. 12, was struck on the head with the back of an axe, causing a contused wound with a crucial laceration, about two inches in either direction, and a fracture and depression of at least three-fourths of the entire left parietal bone. A portion of the middle of the parietal bone, about three-fourths of an inch in width, and two inches and a half long, extending from the temporal side to within an inch of the sagittal suture, was found entirely disconnected, and its posterior edge so depressed that the fragment stood perpendicular in its short diameter, showing a depression of its entire width—three-fourths of an inch. The anterior or temporal edge of the portion of the parietal back of this was depressed to a like depth, and at its junction with the right parietal, about a line, from which, however, it was not entirely detached, the periosteum being intact. The detached fragment was removed. The remainder of the depressed portion, by sawing off a small point of bone, he was able to raise to its position. There was no laceration of the dura mater. With a view of promoting suppuration, and giving a free outlet to the pus, he approximated the edges of the flaps to about the tenth of an inch by means of adhesive straps, and ordered the application of warm flaxseed poultices enclosed in a flannel cloth. Twenty-seven days following the in-

jury, the wound healed. Complete convalescence followed without an unfavorable symptom.

His opinion is that all wounds of the head, with fracture of the cranium, that we cannot expect to heal by "first intention," should be treated as suppurating wounds from the beginning, with warm applications instead of cold, and that less extensive inflammation will follow after this mode of treatment.

MERCURY IN VULCANIZED RUBBER PLATES.—As the assertion is often made "that mercury contained in dental plates made of india-rubber" is very poisonous, Jas. B. Hodgkin, D.D.S. (*Am. Journ. Dental Science*), wishes to relieve the minds of those wearing rubber plates, and states that the mercury, so-called, is not mercury in fact, any more than cider is vinegar, or starch is sugar. "Vermilion" is the preparation necessarily used by the manufacturers of india-rubber to give that article the ordinary red tint. This is the sulphuret of mercury, Hg. S., containing equivalent proportions of mercury and sulphur, an insoluble compound under ordinary circumstances.

In a rubber dental plate we have, on an average, 45 grains of sulphuret of mercury firmly combined with rubber, in such a form that it cannot be reduced to the metallic or soluble condition except by a degree of heat sufficient to sublime the mercury, which takes place at 662° F., and this, of course, could not occur in the mouth, when it is remembered that water boils at 212°. No other change can occur but this; and this leaves but one other source of danger of mercurial poisoning, and that would be from the wearing away of the plate, and the consequent swallowing of the particles thus worn off. As these plates last from ten to fifteen years, and they do not wear out, but fail from some molecular change in the rubber, it will be apparent that this danger is not great.

ALVEOLAR ABSCESS.—At the April meeting of the Southern Dental Association, held in New Orleans, La., a profitable discussion ensued on alveolar abscess, and Dr. J. S. Knapp advised the use of creasote in alternation with chloride of zinc.

Dr. Clarke, of Savannah, recommended carbolic acid, iodine, and glycerine.—*Am. Journ. Dental Science.*

FRACTURE OF THE INFERIOR MAXILLARY.—R. Wisong, M.D., Baltimore, Md. (*The Med. Bulletin*), publishes a case of this character, with the application of the modification of Dr. Bullock's sub-maxillary splint, made by Dr. R. B. Winder, a Baltimore dentist. Dr. W. took in wax an accurate impression of the lower jaw, and manufactured a vulcanized rubber splint which fitted over and covered all the teeth except those at the point of fracture. The teeth were allowed to show. This arrangement enabled the surgeon to see at a glance if the fractured ends were in juxtaposition; for, so long as the teeth were in line, there could be no displacement. This opening also enabled him to syringe out any accumulation of food or secretion between the splint and teeth or gums. The object in covering all the teeth, except at point of fracture, with the dental splint was, that they, instead of the gums or alveolar processes, might receive the pressure.

To this dental splint two stout wire hooks were attached, which came out at the corners of the mouth. To these pieces of annealed wire were fastened, instead of cords, as recommended by Dr. Bullock, which extended below the sub-maxillary splint. These were secured with thumb-taps. With this arrangement the pressure could be graduated with greatest nicety. This splint allows the patient to eat and talk without fear of displacing the fractured ends of the bone.

OVARIAN NEURALGIA.—Dr. J. T. Newman (*Chicago Med. Examiner*) recommends the following prescription in this affection:—

℞	Ammoniæ muriatis,.....	ʒ ij.
	Tr. aconiti,.....	f ℥ ij.
	Syp. aurantii cort.....	f ʒ viij.

M. S.—Teaspoonful three times daily.

THE SUCCESS OF GALVANO-PUNCTURE.—The success of the operation in aneurism depends on the subjoined conditions, viz.:—1st, The size of the aneurism; 2d, a proper insulation; 3d, the exact amount of galvanic force.

A proper covering of the needle by some non-conductor is of the utmost importance. If this is not carefully attended to, the heat produced by a large exposed non-conducting surface will give rise to a violent secondary inflammation, so severe that the entire sac may subsequently slough away. The sloughing of the track of the non-insulated needle is another deplorable danger. To prevent these dangers the needle has been insulated by various substances with indifferent success. Petrequin recommends wax; Brocca, shellac; Phillips, black enamel.

Allen Mc Lane Hamilton, M.D., in his "Prize Thesis," presents the following formula for successfully coating the needles:—

℞	Gum shellac (Brown).....	1 drachm.
	Sol. india-rubber (Squibb's).....	1½ "
	Chloroformæ.....	2 "

M. The force and power of the galvanic battery should be carefully regulated. Too great an action may form a very curdy, loose clot, easily broken up by the circulating blood, carried off as emboli.—*Hamilton's Prize Thesis.*

PREPARATION OF CHLORAL.—The best mode of preparing it in a pure state is to subject absolute alcohol to the action of dry chlorine. Great precautions are requisite, since, in order to act upon about half a pint of alcohol, 1200 litres of chlorine are required, and 1500 litres of disengaged hydrochloric acid have to be disposed of. The chlorine, pure and dry, is transmitted through the alcohol contained in a large flask, from which an escape pipe leads to a large chimney. At first all the chlorine is converted into hydrochloric acid; but as the action becomes less energetic, the alcohol assumes a yellow color, which, however, disappears on the introduction of a few fragments of charcoal. The temperature of the alcohol must then be steadily and continuously raised, whilst the current of chlorine is rapidly passed through the fluid, till almost its boiling point is reached. In twelve hours about six ounces of alcohol can be converted into chloral; but when larger quantities are required, the operations must be continued for two or three days. The liquor in the flask is mixed with two or three times its volume of concentrated sulphuric acid, and submitted to careful distillation, in order to free it from hydrochloric acid, sulphuric ether, and alcohol. As soon as the temperature rises, the chloral accumulates at the surface of the mixture, and rapidly volatilizes. The distilled chloral is then placed in a retort with a thermometer, and boiled till its boiling point, at first lower, rises to 94° or 95° C. The remaining liquor should be redistilled with sulphuric acid, and again boiled. Lastly, it is to be distilled in a bath of common salt, after the addition of a small quantity of lime. To obtain the hydrate, it is only requisite to mingle it with its own volume of water, and evaporate.—*Lancet.*

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, July 15, 1870.

THE CONVENTION OF MEDICAL TEACHERS, AND THE PRESENT ASPECT OF THE MEDICAL EDUCATION QUESTION.

HAVING just received a full official report of the proceedings of the Medical College Convention, recently held in Washington, we are again invited to bring the general question of medical education, particularly that referring to the requirements of our medical schools, before our readers. This we do with no possible feeling of reluctance; on the contrary, convinced that it is our duty to further every feasible plan of reform, we gladly seize the opportunity thus offered. At the very outset, however, we are compelled, on behalf of the faithful pioneers of medical educational reform, merely to report progress. But even this is encouraging, taking into account all the various opposing circumstances that have been thrown against the adoption of the measures originally proposed.

Our readers are not ignorant of the passage of a set of resolutions at the Convention of Medical Teachers held in Cincinnati, May 3, 1867. The propositions embodied in those resolutions were designed to introduce into the system of medical college instruction many radical changes:—I. A positive standard of preliminary education was insured by a requirement to the effect that every gentleman intending to enter a medical college should be "required to show, either by satisfactory certificate, or by direct examination by a committee of the faculty, that he possessed a knowledge of the common English branches of education, including the first series of mathematics, the elements of the natural sciences, and a sufficient knowledge of Latin and Greek to understand the technical terms of the profession; and that the certificate presented, or the result of the examination thus required, be regularly filed as a part of the records of each medical college. II. That every medical student should be required to study four full years, including three regular annual courses of medical college instruction, before being admitted to an examination for the degree of Doctor of Medicine. III. That the minimum duration of a regular annual lecture term, or course of medical college instruction, should be six calendar months. IV. A systematic and successive order of studies—the students being divided into three grades, freshman, junior, and senior; and V. A special provision for clinical instruction in hospital to the senior students.

A committee of five, consisting of Drs. N. S. Davis, of Chicago, S. D. Gross, of Philadelphia, F. Donaldson, of Baltimore, the late Alden March, of Albany, and G. C. Blackman, of Cincinnati, was constituted, to communicate with the different medical colleges throughout the country, in order to ascertain the views of the respective faculties of the same, and, if possible, to agree upon some concerted action on the premises. The whole question was at the time fully discussed in the columns of the RECORD; and it will not answer our present purpose to do more than refer our readers to the arguments offered for the adoption of the different propositions therein contained.

There did not seem to be any powerful objection against its practical endorsement by the medical colleges throughout the country, except, perhaps, the foreshadowed one of a failure to agree on all the points presented. The experience of three years in the discussion of this matter, and in collecting the opinions from the faculties of the several schools, has proved that this want of a disposition to combined action is the main if not the only reason why the report has not been practically accepted. This fact is fully set forth in the able report of Dr. N. S. Davis, the Chairman of the Committee of Five. As a history of the educational movement thus far, it is a valuable piece of experience, as showing the ordinary and usual difficulties attendant upon all efforts to reconcile personal interests with the public good.

Notwithstanding all the medical colleges were invited to offer any objections or amendments they might think were necessary, only about ten of the thirty or more institutions then in active existence responded at all. Of these only five sanctioned the movement unequivocally, and declared their determination to act upon their convictions when a majority of the colleges should agree to combine with them. One institution was non-committal, and four suggested amendments. Virtually but one-third of the medical institutions throughout the country paid any attention whatever to the circular, showing pretty conclusively how dear to the heart of most of our medical teachers is any attempt at elevating our standard of acquirements. Experience has also proved that the settlement of the question of advancing medical learning must for the present rest entirely with the colleges, and that neither the American Medical Association nor the general government can affect it a particle. The profession are in reality in the hands of educational monopolists, the majority of whom have clearly shown themselves by their recent action to be insensible to anything in the shape of reform that may interfere with their pecuniary interests.

Here we have an appeal from a committee appointed from a most respectable assembly, with full authority to treat on questions which concern the vital interests of the profession at large, and only ten medical schoo's respond. The remainder, among which are some of the leading colleges in America, do not deign to give it even the cool courtesy of a recognition. In view of this the faint-hearted may get discouraged; but we are convinced that the time will come when the current of professional opinion will set in a direction that will be felt even by the largest and oldest schools, and that we shall yet have the opinions of the leading minds in the profession practically respected. The representatives of the Convention did not seek for an absolute adoption of their views, but courted the expression of any difference of opinion on the subject, that such might be made of use in perfecting the system. The delinquent schools owe it to their self-respect, in case they differ on radical points, to state them candidly, else they open themselves to the suspicion that they dread light to be thrown on their doings. They owe it to their reputation to place on record at least a sympathy for the movement, even should they feel powerless at present to practically test it by the changes proposed.

The last Convention, although at a convenient time and place, was very sparsely attended, and its proceedings, as we have before intimated, amounted to nothing. The reason seemed to be that some of the delegates from the Northern and Eastern Colleges had no authority to commit themselves on behalf of their respective faculties. And this was the case, despite the fact that the circular had been before every faculty in the land for the past two years for discussion. Many of the delegates from the South and West had come prepared for a final action, and were obviously very much disappointed to find that the brethren from the larger colleges took so long to make up their minds. It is not very difficult to see where the responsibility in this matter rests, especially when we are made aware of the fact that the old colleges of New York, Boston, and Philadelphia were *not* committed to any policy whatever.

In glancing over the proceedings we noticed the passage of the following, offered by Prof. Stillé:—

"*Resolved*, That, in the judgment of this Convention, the propositions adopted in 1867, by the Convention of Delegates from Medical Colleges, embody a system of collegiate medical education in the highest degree commendable, and which, if they could be generally carried into effect, would tend to elevate the medical profession,—that, nevertheless, the requirements for the degree of Doctor of Medicine must be practically determined by each Medical College for itself, by the average attainments of its students, and by other considerations of which it alone can judge; and that, consequently, while abstaining from all attempts at dictation, this Convention reiterates in the strongest manner its desire that the several Medical Colleges will, in the changes from time to time made by them in the curriculum of study, endeavor to conform them to the general plan which was recommended by the Convention of 1867, and adopted in the same year by the American Medical Association."

This is certainly conservative enough, and we hope that it will prove the entering wedge for better things in the future.

By way of placing on record the transactions of the Convention in question, at the same time giving an idea of its future efforts, we conclude with copying entire the following, offered by Prof. Samuel Logan, giving at the same time our hearty approval of the measures:—

"*Whereas*, This Convention has failed to secure the assent of a majority of the regular Medical Colleges of the United States to the system of improvement in medical education recommended at its last session; and,

"*Whereas*, It is the opinion of this Convention that the best means by which a judicious system of gradual improvement in medical education can be inaugurated by the Medical Colleges of this country, will be found in the *associated action* of such Colleges as will unite for that purpose; it is hereby

"*Resolved*, 1st. That a committee of nine be appointed, whose duty it shall be to communicate with the Faculties of all the regular Medical Colleges in the United States, with a view to ascertain how many, and which, may be willing to become members of an *Association of Medical Colleges*, having for its prime object the improvement of medical education.

"2d. That the Chairman of said Committee be instructed, as soon as he shall have received affirmative replies from ten (?) regular Colleges, to inform each Faculty so consenting of the fact, and to request that each Faculty elect one or more delegates, to convene on the Friday before the day appointed for the meeting of the American Medical Association, in 1871, and at the place of meeting chosen by that body—said delegates to be fully authorized to pledge their respective Faculties to whatever definite plan of improvement in medical education may be adopted by the body in Convention.

"3d. That it is hereby recommended that said delegates organize themselves, in behalf of their respective institutions, into a permanent *Association of Medical Colleges* for the above-mentioned object, and with the view of co-operating with the American Medical Association and the profession at large, in efforts to accomplish so desirable an end.

"4th. That Prof. N. S. Davis, the Chairman of the Committee appointed by the Convention of 1867 to communicate with the Medical Colleges on the same subject, be made the Chairman of this Committee, and that the Committee be authorized to fill any vacancies which may occur in its ranks."

Those who were present as delegates at the late meeting of the American Medical Association, in Washington, D. C., and heard the wrangling between the Massachusetts delegates in regard to their admission in that body, will be gratified to learn that at the June meeting of the Massachusetts Medical Society the following resolution of Dr. Bundy, of Boston, and amended by Dr. H. R. Storer, was passed:—

Resolved, That the Massachusetts Medical Society hereby expels from fellowship all those who publicly profess to practise in accordance with any exclusive dogma, whether calling themselves homœopaths, hydropaths, eclectics, or what not, in violation of the Code of Ethics of the American Medical Association.

As we understand the case, the Statutes provide for the admission of irregulars into this body. If we are right, such a resolution does no more than record the expression of an opinion. We sincerely hope that the contrary will prove to be the case, and some practical good may come of it.

Reviews and Notices of Books.

A Treatise on Medical Electricity, Theoretical and Practical, and on its Use in the Treatment of Paralysis, Neuralgia, and other Diseases. By Julius Althaus, M.D., etc. Second edition, Revised and partly rewritten. London: Longmans, Green & Co. Philadelphia: Lindsay & Blakiston, 1870. 12mo, pp. 676.

Dr. Althaus is a pioneer writer in Great Britain on the medical uses of electricity. Ten years ago he published the first edition of this work, and, as he writes in his preface to the present one, at that time medical men held galvanism in very low estimation; "reports of cures by electricity were received with an incredulous smile; there was only one hospital—Guy's—where electricity was regularly used, and there it was applied in an antiquated fashion, and its use relegated to nurses or dressers." We of New York need not go very far from home to see the same state of things. But Dr. Althaus tells us that in London there is a great change: "At the present time not a few hospitals possess the necessary electrical apparatus; able teachers are instructing students in its scientific applications; and the first medical society in the kingdom has appointed a committee composed of some of the most eminent members of the profession for investigating the therapeutical uses of electricity." May we not hope for some general professional movement in the same direction in this country? The few practitioners who own its worth, and understandingly employ it, are still looked upon as bidding for popular favor by unlawful, or at best doubtful, means, by the conservative majority, who in every age and in all places have claimed the right of blessing or anathema on those whose views may not fit their own inelastic dogmas. It is in vain to tell such that the scientific aspect of the subject has materially changed during the past decade; that, consequently, its practical aspect has been better studied by many of the best men in the profession; and though far from perfect, its state is one of happy and promising progress. We believe, and our opinion has been formed by no small study or inconsiderable experience, that individual tact, the result of personal practice, which includes both knowledge and wisdom, or the ability to value and use knowledge, is as necessary as an understanding of what is taught by others. The general rules are yet, to a degree, uncertain; each physician who employs the different forms of electricity as therapeutic agents, must, more or less, solve many of the problems himself; he should be prepared for disappointment, or even untoward events, in cases to all appearances alike, and the often slight shades of difference which affect the result can only be learned by personal study. There is no mystery nor hocuspocus in the use of this agent; but it becomes unsure, or even dangerous, when of hap-hazard employment. One prevailing notion is, because the disorder is a palsied limb, therefore electricity is the remedy; no heed being taken of the kind of palsy existing, or, what is just as important, the kind of electricity used, or the degree of both, and so on. It is this empirical employment of the remedy which has made the professional rating of it so contradictory and unsatisfactory. With such a book as Dr. Althaus', in which both the scientific and practical aspects of the subject are ably, concisely, and thoroughly treated, open to him, the physician who chooses to inform himself has no excuse for future ignorance. It is much the best work treating of the remedial effects of electricity that there is in English, and we hope it will be widely read and understood. The different circumstances and conditions which require the several varieties of current, singly, or combined, or alternately, are well given, and, on the whole, the author's claims of what may be accomplished by electricity will hardly be considered as exaggerated by those who know the capabilities of the agent when intelligently employed.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 8, 1870.

Dr. J. C. Hutchison, President, in the Chair.

FIBROMA UTERI.

Dr. Hart exhibited, on behalf of Dr. T. A. Emmet, a specimen of fibrous tumor of the uterus, and read the following history of the case:—

Fannie Phyfe, æt. 46, born U. S., was admitted January 20th, 1870. Married 16 years, has had two children, never miscarried. First child born twelve years ago, second child born ten years ago. Menstruation first appeared at the age of thirteen, recurred regularly, generally lasting a week. Leucorrhœa never a troublesome symptom. About two years ago first noticed that the menstrual flow was too copious, since then it has been gradually becoming more and more free. Last June she suffered pain for the first time with her period, now she is hardly ever free from a show. This state of things has existed for the last three or four months; general health has been excellent; has a good appetite; bowels regular when she has been able to be up and take proper exercise. Pathological condition: fibrous tumor attached to the anterior wall of the uterus by a broad base. February 15th, Dr. T. A. Emmet examined the attachment of the growth, with a view of its removal by the scissors, the uterus being previously dilated by sponge tents. He determined, however, that it had such a broad base that an operation was not justifiable at that time. Dr. Macready, her former physician, was present at the time of the examination, and fully concurred in Dr. E.'s opinion that the removal of the growth should be deferred until it had become pedunculated.

This time, however, never arrived, as it was finally removed with a scissors.

STAB WOUNDS OF HEART AND INSTANTANEOUS DEATH.

DR. FINNELL presented three specimens of stab wounds of the heart. The organs were respectively removed from a murdered man and woman, and a suicide. The latter discovered his wife in the company of a male friend, was forthwith seized with an attack of moral insanity and stabbed both of them, afterwards despatching himself. All the wounds were confined to the respective hearts, and in the friend and the wife they were very much alike, the knife entering the left auricle and passing out of the left ventricle. The heart of the suicide was opened from the apex of the left ventricle to its base. Death occurred in each case in a very few moments.

DR. DETMOLD asked, What was to be understood by "a very few moments?" and remarked that death generally took place instantaneously when the auricle was injured.

DR. FINNELL replied that such a short space of time could not be calculated, although the parties who were present stated that no effort at breathing was made after the wounds were inflicted. In answer to Dr. Van Gieson, as to the size of the external wound, he remarked that he had no positive recollection, as the specimens were some three or four months old.

BULLET WOUND OF HEART AND RECOVERY.

DR. HART referred to a specimen of wound of the heart, of a character similar to that of Dr. Finnell's, caused by a ball, in which, however, death was not the result. The missile had passed through the right auricle, thence through the septum, and was lodged on the left aspect of the apex. It was not known how long the ball had remained in that situation, as it was only accidentally found after the animal was shot a second time. The animal was a deer.

DR. DETMOLD stated that there were a number of cases on record similar to the above, in which in the deer encysted bullets had been found in the heart. In this connection he recalled the case of a soldier mentioned by Larrey. The patient had received a wound in the region of the heart, and while seemingly convalescent therefrom suddenly dropped dead. At the autopsy the ball was found free in the cavity of the ventricle, it having evidently been primarily imbedded in one of the ventricles. Death was apt in wounds of the ventricle to be very tardy, on account of the thickness of the muscular walls and their tendency to close over the missile.

THE BULLET IN THE HEART FOR TWENTY YEARS.

The discussion recalled to the mind of Dr. Rogers a case reported to the Society by Dr. Hamilton two years ago (vid. MEDICAL RECORD, vol. ii., p. 18), in which a ball had been found in the walls of the heart, near the apex, twenty years after the injury had been inflicted, death having occurred from an accidental pneumonia brought on by exposure. In the discussion which followed that case, an opinion was expressed to the effect that the ball having entered the right shoulder from above, had gone into one of the large vessels, dropped down into the heart cavity, afterwards penetrating the endocardium. Some weeks after the presentation, Dr. Hamilton informed Dr. R., as the result of a careful dissection, that he had become convinced from the obliteration of the jugular vein that such a theory as to the transit of the ball was the correct one.

INCARCERATED HERNIA AND INEBRIETY.

A second specimen consisted of the parts involved in femoral hernia, removed from a woman aged 45, who for three or four days had suffered (according to the account of her friends) from all the symptoms of femoral hernia, being all that time in a beastly state of intoxication. She apparently died as much from the drinking as from the trouble in the gut. On examination after death, a large tumor was discovered in the left inguinal region, due to a femoral hernia, involving two feet of intestine. It was reduced without the slightest difficulty, and there were no other signs of trouble save an intense redness of the mass. It seemed evident that it was nothing more than an incarcerated hernia, which could have been very easily reduced during life.

ANOMALOUS CASES OF STONE, LITHOTOMY, ETC.

DR. DETMOLD presented a specimen, and gave the following history of the case to which it belonged:—

On the 20th of April a boy aged 3 years was brought to the clinic suffering with all the symptoms of stone in the bladder. A small bent silver probe was introduced and a stone discovered. This was followed by a tolerably large-sized staff, which passed in with perfect ease. Several army surgeons who were present likewise felt and recognized the existence of the stone. Dr. D. then proceeded to operate by the lateral section, but when he cut into the bladder no calculus was to be found. Before commencing to operate he had occasion to remark that the case was in some of its aspects a little different from ordinary ones, inasmuch as the staff did not bring out the usual metallic ring, but in its stead a sensation as if it encountered some sort of incrustation, and that he was sorry to say that he had neglected to bring a calculus with him in case he should fail to get one from the operation. The finger being introduced with a negative result, the sound was again employed, when he found, just above the incision, the same sensation of grating against some hard substance. He then made an incision upwards with a grooved knife, then with the finger nail he scratched a little, and a stone weighing seven grains fell into the wound.

He remarked that this case might have been an example, perhaps, of many in which surgeons had failed to find the stone after a clear diagnosis had been made, never thinking of looking for the calculus in the membranous portion. It was remarkable that in a child of that age so large a staff should pass in without resistance.

As a companion to the former, he exhibited another stone, removed by operation from a boy brought to his clinic on the 1st of June. The patient was 15 years of age, and was laboring under all the ordinary symptoms of stone in the bladder. After the patient was placed upon the table the doctor proceeded to introduce a metallic staff, and feeling at the same time a hard body in the scrotum, remarked to the class that one of the testicles was very much indurated, accounting for the condition by the constant straining to which the patient had necessarily subjected himself. The sound, however, was suddenly arrested in its progress, and could not be made to go any farther. Examining the hardened body with more care, he found that instead of its being a testicle it was in reality a stone of large size, which hung down into the scrotum far enough to enable him to isolate it by a grasp. It was situated in the bulbous portion of the urethra, and was removed by an incision direct upon the part, through which a portion of the corpus cavernosum made its appearance. Both of the testicles had been drawn up in the abdominal ring. The calculus weighed half an ounce.

Both the cases perfectly recovered. In concluding his remarks upon these, he referred to the strange fact

that two such unique ones should present themselves within two weeks of each other.

BILIARY CALCULUS HALF AN OUNCE IN WEIGHT DISCHARGED PER VIAS NATURALES.

He also exhibited a calculus, biliary in character, weighing half an ounce, which had been brought to him by a physician in order to have its character determined. The patient was described by the attendant as having suffered a great deal of pain and distress during the passage of the stone, but more particularly at the time of its escape from the anus. The specimen was the largest that he had seen that had been passed *per vias naturales.*

DR. ROGERS thought it remarkable that in the first case of Dr. Detmold there was no obstacle to the passage of an instrument. Dr. R. recollected a case which he had in a young infant, with a very much smaller calculus in the urethra, in which it was impossible to introduce the smallest-sized probe. Relief could only be afforded by extraction through an external incision.

CANCER OF LIVER, STOMACH, ETC.

DR. MERRITT exhibited a portion of the liver and the stomach removed from a German, æt. 35, who until two years ago enjoyed excellent health. At that time he first began to complain of attacks of gastric and hepatic derangement, which soon increased in frequency, and became attended with an exceedingly irritable stomach. He had been under the care of a homœopathic attendant for a considerable period, and did not present himself for regular treatment until three or four weeks since. When Dr. Merritt first saw him, he found him considerably emaciated, icteric, with a feeble pulse, distended and ascitic abdomen, and a liver which extended far on the left side, nearly down to the level of the crest of the ilium. It was hard and firm, and apparently smooth. He could hold nothing on his stomach, and finally died as the result of inanition.

Autopsy thirty hours after death. The cavity of the abdomen contained about six quarts of fluid of a pale yellow color. The liver was studded with pale yellow masses composed of a sero-purulent fluid, and weighed sixteen pounds. The mesenteric glands were involved, as was also the œsophageal extremity of the stomach, where an ulceration existed. Here and there through the lungs the same masses were found. The spleen was contracted and the kidneys normal. The heart was slightly enlarged, and there was a slight atheromatous deposit on one of the curtains of the mitral valve. The masses were found on microscopic examination to be cancerous in character. The largest specimen of medullary cancer of the liver spoken of by Paget was 250 ounces; this one weighed 256 ounces. There was no hereditary predisposition to cancer.

CIRCUMCISION VERSUS EPILEPSY, ETC.

DR. SAYRE presented the prepuce of a youth aged 16, removed by circumcision ten days before. For the past two years the patient had suffered from epileptic convulsions, which for the last eight months were constantly increasing, attended also with an increasing loss of muscular power of the lower extremities. On examining his genital organs a large prepuce was found, with a very small opening, through which urine escaped with great difficulty. This latter was so great that the prepuce became greatly distended, compelling him to milk it to relieve himself. Once or twice there was an inflammation of the lining membrane of the prepuce, resulting in adhesions to the glans. Presuming this to be a source of irritation he determined to circumcise him. Since the operation there had been no convulsions, when before there was scarcely a day without them, and not unfrequently there were four in the course of twenty-four hours. He was inclined to look upon the irritation of the penis and the convulsions in the relation of cause and effect, remarking that too little attention had been given in such cases to the treatment of such genital affections. The following case, bearing on that point, was related in connection with the foregoing: Dr. Sims sent him a patient, with legs contracted at an acute angle, for the purpose of having the hamstring muscles cut. On examination it was found that the limbs could be very easily extended, showing merely a paralysis of the anterior muscles. While preparing to use the galvanic current upon the parts, the nurse warned him to be careful not to touch the child's penis as it was exceedingly tender. He found it very erect and very red, with phymosis, and a very small preputial orifice. On attempting to expose the glans adhesion was discovered. This condition of things, according to the nurse, had existed for a year and a half, giving rise to a good deal of irritation. The case was explained to the father, and he consented to the operation of circumcision. No other treatment was employed, and both limbs soon became perfectly straight. Since that time his attention had been drawn to some fifteen or sixteen similar cases in which a similar treatment had been followed by a like gratifying result. He had performed the operation that day upon two boys with this form of phymosis, who were addicted to wetting the bed, and he had no doubt that there would be a complete breaking up of the habit in consequence.

DR. DETMOLD believed that these adhesions spoken of by Dr. Sayre were of fœtal origin, and that ordinarily no such radical operation as circumcision was required in the majority of cases, all that was necessary being a slitting of the prepuce on one or both sides to relieve the stricture. He believed in relieving the phymosis, but thought that the Dr. broke his egg with a large hammer. He did not mean to be understood as saying that the existence of a prepuce was any great advantage, still there was no reason why it should be needlessly cut away. On the other hand it might be very desirable to preserve it, as it might lead to the suspicion, after marriage with a widow, that the male was either not perfect or had suffered from some disease. In Dieffenbach's surgery there was an operation described for forming an artificial prepuce, which fact proved that the want of that appendage had been seriously felt. Again, if the operation of circumcision were a radical cure for wetting the bed, then Jews would never be addicted to the practice, a fact not borne out in his experience.

DR. SAYRE stated that he had circumcised only three cases for this difficulty, all that was necessary in the remainder being to slit up the prepuce as proposed by Dr. Detmold.

DR. HUTCHISON remarked, that he had had occasion to remove the prepuce for spermatorrhœa, and being informed that the young man whose case was reported by Dr. Sayre had that trouble, he ventured to conjecture that the phymosis might have caused the spermatorrhœa and the spermatorrhœa the paralysis.

DR. DETMOLD stated that there certainly was no objection to circumcision in extreme cases, and slitting of the prepuce in ordinary cases, inasmuch as it was known that phymosis was one of the causes of sterility.

DR. ROGERS referred in this connection to a case in his practice of a man who had such a small opening in

his prepuce that he had never been able to see the glans, but he was the legitimate father of four children.

Dr. Detmold acknowledged that the rule need not always be without exception, but that there were some good authorities who state that phymosis, like every other fœtal condition remaining in after life, was the exponent of a want of power in the particular apparatus affected.

EXFOLIATION OF PORTION OF OS FRONTIS, ETC.

Dr. Sayre next exhibited an exfoliated portion of the os frontis, removed from a gentleman who, six years ago, while passing through a hall ran against a projecting gas-bracket, inflicting a severe bruise on his forehead, about two inches above the right superciliary ridge. This spot was afterwards very annoying, and finally an opening occurred which constantly discharged and refused to heal. When he presented himself to Dr. Sayre a probe easily detected dead bone. An incision was made upon the point, and the foreign body grasped, when it was found to be locked on the inside of the skull by an extra process which seemed to be an exostosis. After its removal the pulsations of the brain were clearly visible. There was no evidence of any syphilitic taint. The wound had not yet healed.

STRICTURE OF RECTUM.

Dr. Hutchison exhibited a specimen of stricture of the rectum, removed from the body of a lady 35 years of age. She came under his observation on the nineteenth of January last, with the statement that for the previous eight months she had suffered from considerable distress in the lower bowel, manifested by pretty constant tenesmus and a discharge of a sanious fluid per anum. Otherwise she appeared to be in excellent health. An examination was made per rectum, when a narrow rim of deposit was discovered on the left half of the intestine about three inches from the anus. On the right side of the bowel and behind it, apparently in the subcellular tissue, another mass was discovered of the same consistency. In referring to her history, no hereditary predisposition to cancer was discoverable, neither had there been, at any previous period, any attack of dysentery or other inflammation of the gut. There was also no reason to suspect syphilis. The diagnosis of malignant disease was made, and she was informed accordingly. Some two or three weeks subsequently she consulted Dr. Van Buren, who found that the rim then extended entirely around the rectum. Some four weeks after his first examination Dr. H. made a second, when he found the whole circumference of the gut involved. So close had become the stricture, that it was impossible to crowd the finger through it. At that time she had had no evacuation for seven days. He began to dilate the stricture with a No. 12 urethral sound, and went on increasing the size of the bougie until the largest size was reached. This was not followed by any considerable discharge of fæcal matter. She suffered a great deal from pain, and indeed experienced no relief whatever. She was not examined again until after her death, which took place five weeks after the last examination, during which time nothing passed her bowels, she being kept comfortable by opium.

As she had expressed a wish not to be buried until the fourth day, a post-mortem examination was not made until that time. The body was well preserved on ice. On opening the thorax two yellowish white spots on the lower portion of the right lung were found, presenting the aspect of medullary cancer. There was also a smaller nodule in the lower lobe of the left lung, otherwise the two organs were entirely healthy. The heart was also normal. On opening the abdominal cavity, the colon was seen distended with fæcal matter from three inches above the caput coli to the point of stricture, the greatest accumulation being at the junction of the ascending and transverse colon, at which point there were numerous adhesions to surrounding parts. The stricture, three inches above the anus, extended upwards, involving about two and a half inches in breadth, and was so close that water could only pass through very slowly by drops. There were some deposits over the bladder, some in the liver, spleen, and right kidney, which was considerably larger than the left. The pancreas and stomach and uterus were normal.

In conclusion, he stated that the operations for excision of the rectum and lumbar colotomy were respectively discussed, but it was deemed inexpedient to employ either—a decision well borne out by the autopsy.

Dr. Detmold asked if primary cancer of the rectum in a female was not exceedingly rare? He had never seen nor heard of one.

Dr. Bibbins recollected one such occurring in Bellevue Hospital, which, on account of its rarity, excited a great deal of attention.

Dr. Rogers had in mind another case of primary cancer of rectum in a female, which had been extensively advertised by the Missisquoi Spring proprietor as having been cured.

Dr. Van Gieson referred to a case of cancer in the rectum, in New Brunswick, N. J., for which colotomy had been performed by Dr. Morrough of that place. The patient died six days after.

Dr. Detmold did not believe the operation was ordinarily justifiable, although in some cases life might be lengthened by it.

Dr. Hutchison referred to one case reported by Mr. Curling, in which that gentleman had supposed that life had been prolonged by it seventeen months.

There being no other specimens, the Society went into executive session.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Reunion, April 8, 1870.

Dr. Isaac E. Taylor, President, in the Chair.

STETHOSCOPES AND THEIR USE.

Dr. Austin Flint, Sr., who had been announced to speak upon *Stethoscopes*, remarked:—

I trust, Mr. President, that none of the gentlemen have come to-night expecting to hear a carefully prepared paper; for I expressly stipulated that I should be allowed simply to make a few off-hand remarks. And I will say at once that I do not propose to enter into any abstruse questions of acoustics; for these, however interesting, and in a certain sense useful, are not important for the practical employment of auscultation by means of stethoscopes.

In selecting the subject of Stethoscopes, I of course imply that I intend to speak only of *mediate* auscultation. But, in thus confining our attention, I would not, for a moment, be understood to disparage *immediate* auscultation, by the ear applied directly to the chest. One who has devoted much attention to this subject is very apt to be asked, Which do you prefer? My answer is, Neither exclusively, for both are important. There are certain advantages, too obvious to require comment, in immediate auscultation—the rapidity and the ease of applying it

when we have no stethoscope at hand. Again, there are important advantages which render mediate auscultation, in certain cases, quite indispensable—the means it affords of auscultating parts of the chest where we cannot directly apply the ear, and of localizing sounds more definitely than by the unaided ear is possible. It is well known that Laënnec studied auscultation altogether by means of conductors; and his great work is entitled "Mediate Auscultation," thus ignoring our ability to ascertain the physical signs by means of the ear alone. He used a wooden cylinder, a little over a foot long, which admitted of being separated in the middle, for convenience of carrying in the pocket. It had a small bore, with a stopper in the end, which, according to his idea, was to be kept in place for auscultation of the heart, and to be withdrawn for auscultation of the respiratory sounds. This particular specimen which I show you is of some interest, as having been owned by Laënnec, and undoubtedly made by his own hand. He was accustomed to amuse himself by turning stethoscopes for his friends. This one was given by Laënnec to one of his *internes*, who, in his turn, gave it to a former colleague of mine, from whom I received it. After these there was made a great variety of wooden stethoscopes. Here is one, made to be used also as a percussor. This delicate instrument, turned from ebony, was used by Walshe, of London, and is the most beautiful I have ever seen.

Dr. Pennock, of Philadelphia, is, I think, entitled to the credit of having first introduced a flexible stethoscope, though of this I am not quite sure. He attached to one end of a flexible tube a metallic cone to be applied to the chest, and to the other end a tube of metal adapted to the external meatus of the ear. I think it was in 1854 that a very important advance was made in the construction of stethoscopes, by the invention of the late Dr. Cammann, of this city. With his "binaural stethoscope" you are of course all familiar. The great excellence of this instrument lies in the fact that it is binaural. That the conduction of sounds is much intensified by this, a trial will easily convince one. So far as I am capable of judging, it seems to me this stethoscope may very well be compared with the binocular microscope. As that brings out objects in strong relief, so this seems to render sounds with clearer definition. In devising the instrument, Dr. Cammann evidently studied very carefully many important points, which are often lost sight of by the different makers. Thus many of the instruments, supposed to be made after his pattern, are so encumbered with defects of construction as to lead to disparagement of the invention itself. Each of the two metallic tubes should have its curves so arranged that the aperture comes in a direct line with the meatus of the ear. The size of the knobs in which they terminate is also important. Of course they must not be too large; but a very common defect is that they are too small, so as to penetrate so far into the ear as to cause pain. In this case it is impossible to use the instrument for any great length of time without much discomfort. The instrument before you is disjointed, simply for convenience in carrying. The flexible part of the instrument should be quite flexible, and this is a very important point. I often see stethoscopes where the tubing appears very nice, but is so stiff as to impair their efficiency; for every motion of the body then pulls upon the ear and causes pain. Again, the tubing should not produce a sound in bending. During the late war it seemed, for a time, impossible to get tubing free from this serious imperfection. The pectoral extremity of the instrument should be made of different sizes. The larger it is, the more sound it conducts; and also the sooner can we pass over the whole chest—a matter of some importance in a complete examination. On the other hand, with a smaller objective, though the sounds are fainter, they can of course be more definitely localized. The conduction is evidently effected chiefly by the air in the tubes. Of this you may convince yourself by obstructing the tubes, or by obstructing one of them, when you at once perceive that the sounds are heard only by the other ear.

I have been led to believe that Dr. Cammann did not appreciate the full value of his own instrument; and I have found a prejudice against it, which I think still exists. Dr. Cammann had the idea that the instrument should be used only where the sounds were too feeble for immediate auscultation, or for conduction by wooden instruments. But it is of great consequence to use it habitually, so as to be accustomed to its indications. Then, again, he had the notion that it impaired the hearing. I am sure that this is not the case, for I have used this stethoscope daily since 1854, and I am not aware that my hearing is in the least impaired. But I can readily see how he gained the idea. For if after hearing sounds through this instrument we try immediate auscultation, the contrast is so great that we fancy the sounds have become diminished in force, or that our power of hearing them has suffered. You must practise in both ways, therefore. It is more trouble, but it is quite essential, to auscultate also with the naked ear, so as to be ready for the cases where you cannot command the stethoscope.

There is one thing about the instrument which explains why so many try it and then throw it aside. I have had, within the last few years, perhaps eight hundred private pupils in auscultation; and my uniform experience has been that the great majority of them, when they first begin to use the instrument, do not like it, and say they hear better with the ear alone; but before the course is over they become so attached to it that I have to enjoin upon them to practise without its aid. This first dislike may be due in part to the fact that both ears are closed, which gives a certain feeling of unnaturalness. But it is due more to the fact that the instrument itself communicates to the ear a certain obscure, somewhat rumbling, sound, not unlike that heard when a shell is applied to the ear. This at first distracts the attention, and it is necessary to acquire the habit of overlooking it entirely—a habit easily acquired. Then, of course, there is something in one's previous habits of auscultation. Any one accustomed to the use of any instrument, however inferior, is apt to think it the best. I began my use of Dr. Cammann's stethoscope in the study of the respiratory sounds of the healthy chest, which I pursued by its means for many months. At that time I used a wooden stethoscope for auscultation of the heart-sounds, though now I know that Dr. Cammann's is particularly well adapted to this purpose.

There have been several modifications of Dr. Cammann's instrument suggested. Here is one given me several years ago, having the pectoral extremity closed by a diaphragm of india-rubber, the objective being filled with water before using. After faithful trial I came to the conclusion that this form had no real advantage that could compensate for its inconvenience. Dr. Snelling, of this city, has attached to the objective a rim of soft rubber, about half an inch wide, increasing the length of the objective by this amount. The advantages he claims are, that you can apply the instrument more closely to the inequalities of the chest, and can make more pressure without pain to the patient, thus improving the conduction and decidedly promot-

ing the patient's comfort. I have used this attachment within the past year, and am much pleased with it. With a large extremity its advantages are very evident. It unquestionably conducts better, and completely meets the difficulty we find, when the walls of the chest are quite thin, in closely applying the objective at every point of its circumference. There is the slight objection that the rubber produces a little sound; but after a short trial you become accustomed to this, so that it does not interfere with you, and hardly constitutes an objection. Dr. Snelling's modification I consider a real improvement.

Dr. Brown, of this city, proposed to have the end of the objective covered with a diaphragm of parchment, firmly stretched, so as to make uniform pressure over the whole circle, and not simply upon its circumference. On testing this, I came to the conclusion that it was of little advantage.

Here we have Dr. Alison's "hydrophone"—a simple rubber bag filled with water, to be used either as the only medium between the ear and the chest, or to be placed in the mouth of the stethoscope when that is applied. With regard to its effect on conduction, which it was designed to improve, I am sure that it is only an impediment, as five minutes' trial will satisfy any one. Dr. Alison, with all the many merits he doubtless possesses, is not, I think, happy in his inventions. Here is what he calls a "differential stethoscope," with two independent objectives communicating each with one ear-piece. His design was to enable the auscultator to listen at the same instant to sounds produced in different parts of the chest. A moment's reflection would show that we must compare sounds not simultaneously but successively; and this is well known to those accustomed to the comparison of musical sounds. Since, then, we can with this instrument listen with but one ear at a time, we lose one-half the conduction.

Lastly, I have to show this contrivance, sent me from Wheeling, Virginia, and called a stethoscope. It is an oval ring of wood, an inch or two in thickness, with one edge covered with velvet, to receive the ear, and an elastic strap to hold it in place on the head. With this curiosity in stethoscopy came a letter explanatory of its merits, such as that it saved the physician's and the patient's modesty, which the direct application of the ear to the chest might offend, etc., etc.

I may venture to offer a few remarks with regard to the question, why some, and I may say quite a number, of those who wish to become good auscultators do not become such. What are the difficulties in the way? The first is that of not pursuing the right course in the study. We have now acquired, if not all the physical signs that will be acquired, at all events a large number of them. These are to be studied by analyzing them into the different elements which they combine as sounds—elements of intensity, pitch, quality, together with some others, such as duration, moisture, etc. The various morbid signs must be compared with each other and with the signs belonging to health, with particular reference to each of the elements which enter into them. It indicates a very loose style of observation, though too common, to describe signs by analogy—to say that such a sound is like so and so.

A great difficulty is that of not giving, as the primary step in the study, sufficient attention to the healthy chest. I have been very much surprised to find how much this is neglected. It is evident that the signs of the healthy chest must be our point of departure; and I never begin a course of instruction without impressing upon the class that they must devote special attention to these. Without a knowledge of them we can, of course, neither distinguish morbid signs from those of health, nor interpret them when recognized. But, clear as this is, I yet find it exceedingly difficult to secure the requisite amount of practice upon the healthy subject.

Another difficulty lies in the inability of some persons to concentrate the attention upon the physical signs, upon the sounds heard. Individuals differ greatly in this regard. But the power of concentration may be acquired by practice, so that auscultation may be performed in the midst of all kinds of noises. By practice the attention may be so directed to a particular sound that no notice is taken of any other.

Yet another difficulty is a logical one, not peculiar to physical exploration—the habit of quickly forming a conviction as to the conditions which exist in the case, and then putting oneself into the advocate's attitude of seeking for evidence to sustain this conviction. I have often seen this. If you interrogate a patient as to his condition, it requires an effort not to form a conclusion—for instance, that tubercular disease of the lungs is present; and then a special watchfulness over your senses to prevent them being misled by your theory into giving you the signs of tuberculosis. I need not say that your proper attitude is that of the judge—that the true method is to suspend judgment entirely until all the evidence is obtained, and then, reviewing it carefully, to make up your decision.

Dr. Farnham thought that the "hydrophone," although an impediment in auscultating the bare chest, was of advantage in conveying sounds more accurately through the clothing. Without it you could not have even the slightest tissue between the stethoscope and the skin.

The President had at one time made much use of the solid cedar stethoscope, and found it of great value, especially for auscultation of the heart and of the abdomen, where he decidedly preferred it to Cammann's. Both Dr. Cammann and Dr. Clark had recommended it for these purposes. It was also of great use in recognizing fractures, where the overlying tissues had become œdematous. There was another instrument, with a very small objective, for placing between the ribs. The profession was indebted to Dr. Flint for reviving the interest in Dr. Cammann's stethoscope, which had been falling into disuse.

Dr. A. L. Carroll referred to a discussion in the *Lancet*, upwards of a year ago, upon the merits of the solid stethoscope of porous wood, called by the younger Liebig the "akouoxylon." He had experimented with a variety of stethoscopes, and found that, practically, air was the best conductor, although this was opposed to the principles of acoustics. He had tried water in Alison's "hydrophone," and had tried hydrogen gas in a stethoscope lined with thin rubber tubing.

Dr. Folsom, referring to auscultatory percussion—auscultation by the stethoscope kept in one place while percussion is made in the surrounding region—said that he had, several years ago, seen it employed in the classes of Dr. Bowditch, of Boston, for mapping out consolidated portions of the lung. He had then thought that it would come into general use, as an additional means of diagnosis, and might lead to important results. It would seem specially adapted to determining with accuracy the degree of enlargement of the heart. If it were advantageous in any case to have a large amount of sound transmitted to the ear, there would seem to be no reason why the advantage should be less marked here. All the experiments he had seen were conducted with Dr. Cammann's instrument.

The meeting adjourned.

Correspondence.

MORBID SYMPATHIES OF THE URETHRA.

To the Editor of the Medical Record.

The Record of June 15 contained an article from the *Med. Press and Circular*, headed "Morbid Sympathies of the Urethra," in which Mr. Paget is represented to say that syncope and epileptiform convulsions never occur on the introduction of the catheter when the patient is lying down.

A few years since I was called in the night to a man suffering from retention of urine. As there were no signs of organic stricture, at first the usual simple means were used. When these failed the man was laid on his back and a soft catheter, bent on itself, easily passed into the bladder. The urine started with great force, but the patient immediately passed into the most violent epileptiform convulsions, when the catheter was withdrawn, and soon the convulsions ceased.

In a few minutes the imperious desire to urinate, with the fearful agony, returned. A second time were simple remedies tried without success, when the catheter was passed a second time, the patient again on his back. Immediately the convulsions returned and the instrument was again withdrawn. The relief was this time a little longer. In less than fifteen minutes, however, the agony returned.

The extreme violence of the convulsions made me hesitate to again introduce the instrument, and the warm bath, pouring water into a shallow vessel, frictions with belladonna, etc., were vainly tried. The patient at length begged me to once more pass the instrument.

When the urine started, my thumb was placed over the end of the catheter, and the urine permitted to escape drop by drop; after a little time several drops were allowed to escape before the flow was interrupted, and the quantity slowly increased until the bladder was empty, with no further return of the convulsions.

Respectfully,
C. B. Hutchins, M.D.

Buffalo, July 1, 1870.

New Instruments.

NEWMAN'S NEW GLASS ATOMIZER.

The atomizer of Dr. Robert Newman, of New York, is constructed on the principle of one capillary tube enclosing another. The double-air chamber of the rubber tube presses the air through the inner tube *r r*, and directs the spray. The same movement exhausts the air from outer tube *p p*. As soon as there is a vacuum in the outer tube, the fluid from the vial *S* is forced upwards into it, and surrounds the inner tube. The continued pressure forces the fluid through the small opening, and produces the spray. The fluid is carried in the outer tube—the air, which atomizes, in the inner tube. The opposite mechanism, *i. e.*, the inner tube carrying the fluid, and the outer the air, will produce the same effect. Instruments constructed according to the latter theory have been made by the same artist, and work well. These atomizers are made to direct the spray in different ways: upwards, downwards, or straight forward. Either of these directions is produced by the end of the inner tube, which conveys the air. But in either case the instrument is only one piece of machinery. Fig. 1 represents the straight atomizer in operation. *p p p*, is the outer tube—*r r* inner tube. *S* the vial with the medicated fluid.

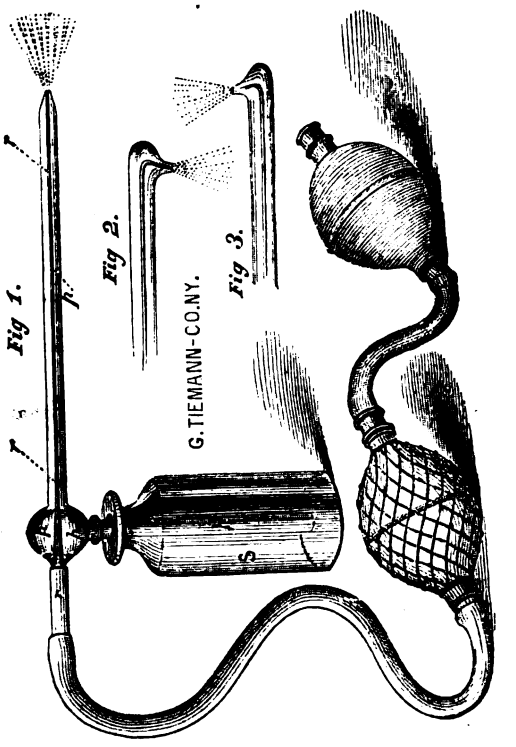

Fig. 2 is the end of an atomizer downwards for the larynx, etc., and Fig. 3 the end of an atomizer which sprays upwards for the posterior nares.

These instruments possess many advantages over all the other patterns in use now. They are clean, always keep so, and they do not decompose the solutions; produce a finer spray, thereby not irritating the parts; never need repairs, always keep in order, and are cheaper than other contrivances. They are not patented.

The idea for the construction of these atomizers was given by Dr. Robert Newman, of this city, and after repeated trials and experiments was executed by Mr. Demuth, the artist in glass.

The instruments are for sale at the well-known instrument-makers', Geo. Tiemann & Co., 67 Chatham street, N. Y.

Medical Items and News.

Prizes by Medical Society, State of New York.—At the Annual Meeting of the Medical Society of the State of New York, held in Albany, February, 1870, a prize of one hundred dollars was offered for the best essay on any medical subject. Also a prize of one hundred dollars was offered by Dr. Hiram Corliss for the best essay on the Cause, Prevention, and Cure of Tubercular Phthisis. Both essays must be sent to one of the Prize Essay Committee by the first of December next, and be subject to the regulations of the Society regarding Prize Essays, as found on page 71 of the Transactions for 1869.

Wm. H. Bailey, M.D.,
Secretary.

NEW YORK TUMOR DISPENSARY.—At the meeting of the Trustees of this Institution, on the 18th of June, the following officers were elected: Pitt Cooke, President; D. J. Justice, Vice-President; Nath. Jarvis, Jr., and John B. Van Vliet, Secretaries; D. W. Mannering, Jr., Treasurer. *Attending Surgeon*, J A. Hagy, M.D. *Consulting Surgeons*, T. Addis Emmet, M.D., and J. C. Nott, M.D. The trustees will open the Dispensary at 101 East 30th st., cor. 4th av., from 9 to 12 A.M., for the benefit of indigent persons afflicted with cancers, tumors, and diseases of a kindred nature.

NATIONAL MEDICAL CONVENTION FOR THE REVISION OF THE PHARMACOPŒIA.—At the late session of this Convention at Washington, D. C., May 4th and 5th, the following permanent officers were elected:—President—Dr. Jos. Carson, Philadelphia; Secretary—Dr. John C Riley, D. C.

The subjoined committee were appointed to revise the Pharmacopœia, with Dr. Carson, President of the Convention, as Chairman:—Dr. G. B. Wood, A. B. Taylor, J. M. Maisch, Dr. R. Bridges, Philadelphia; W. M. Smith, N. Y.; A. E. Ebert, Chicago; J. T. Moore, Baltimore, Md.; G. F. H. Markoe, Boston, Mass.; Dr. J. C. Riley, D. C.; Dr. J. C. Jenkins, Louisville, Ky.; Dr. C. A. Lee, Buffalo, N. Y.; Dr. J. S. Wellford, Richmond, Va.; W. F. Wentzell, San Francisco, Cal.; W. S. V. Ruschenberger, U. S. Army and Navy.

ORGANIZATION OF THE BOARD OF POLICE SURGEONS OF New York.—A meeting of the Board of Police Surgeons was held June 27th, in their rooms, at the Central Police Office, when an organization was effected in accordance with the rules of the Board of Police, by the election of the following officers:

Drs. Fessenden N. Otis, President; Patrick W. McDonnell, Vice-President; Martin Freligh, Treasurer, and Alfred N. Beach, Secretary.

THE WEST VIRGINIA MEDICAL SOCIETY held its annual session in Parkersburg, June 1 and 2. Papers were read by Drs. Safford, Sharp, Hildreth, Roemer, Lazzell, and Nicklin. Dr. U. J. Bland, of Weston, is elected President, and Dr. James W. Lazzell, of Fairmount, Secretary. The next place of meeting is at Martinsburg, Va.

SIR JAMES CLARK, Bart., whose death on the 30th ult. was announced by cable, was the son of a farmer, and born in Banffshire, Scotland, in 1788. On leaving King's College, Aberdeen, he completed his medical education at the Edinburgh University. He afterwards spent some years in the navy, and in 1820 settled as a physician in Rome. In 1826 he returned to England and settled in London, where he soon acquired an extensive practice. On the death of Dr. Maton he was appointed physician to the Duchess of Kent and the Princess Victoria. On the accession of Victoria to the crown she appointed Dr. Clark her first physician, and created him a baronet. He was also physician in ordinary to the late Prince Albert. He was the author of works on climate, consumption, &c., and was a member of the senate of the University of London.

M. AUZIAS-TURENNE.—This indefatigable inventor and propagator of syphilization has just died at Paris, and is much regretted by his friends. Although he defended a system of treatment condemned by the great majority of medical men, he cannot be denied the merit of originality and perseverance. The deceased acted in perfect good faith as regards his theories, and honestly defended what he believed to be true. He had often been taunted with refraining from applying his remedy to himself; but he was always silent on the subject. But it was found, say the medical papers, that he had a great number of scars upon his body, caused by inoculations of chancres. He was buried, according to his wish, without any religious rite; and he has directed in his will that his body should be dissected, and his skeleton, carefully set up, he offered to the medical faculty of Christiania, where his doctrines had, in Dr. Boeck, found such a powerful advocate. M. Auzias-Turenne, unlike many promulgators of new medical doctrines, was not in good circumstances, and has died poor.—*Lancet*, June 18.

INSANE PERSONS IN PENNSYLVANIA.—Estimating the population of this State at 3,500,000, the number of the insane will be 5,833—one in six hundred. One-third of these may not need hospital treatment. Deducting these, we have 3,889 for whom some hospital provision is required. The number of patients in the proper hospitals and asylums is about 1,700, so that there still remain 2,189 who are without the only suitable care and treatment.—*Am. Jour. of Insanity*.

THE PHYSICIAN'S EQUIPAGE.—In Queen Ann's reign, no physician with the slightest pretensions to practice, could manage without his chariot and four, sometimes even six horses.

ANOTHER NEW MEDICAL JOURNAL.—A new monthly medical journal, hailing from St. Paul, Minn., containing twenty-four pages—of which fifteen pages are devoted to original papers, has been received and placed on our exchange list. It is to represent the Profession of the North-West, and is ably edited by Alexander J. Stone, M.D., of St. Paul.

A CHEMICAL PRIZE.—The Trinity College Chemical Prize for 1870, is awarded to Mr. Percy S. Bryant, of the Senior Class. Subject—"Artificial Light."

INFANT MORTALITY FROM SMALL-POX IN PARIS.—The Paris correspondent of the *Chicago Medical Journal* writes that this epidemic has clearly shown that the mortality is very great when attacking children during the first year of their existence—ten times greater than between the ages of 20 and 30. It has been especially very destructive to children under the age of three months—thus showing that vaccination ought always to be done as near birth as possible.

DEATHS FROM URINARY CALCULI.—From the "Report of the Metropolitan Board of Health for 1869," we learn that there were only three deaths from this cause in the year 1869. The same number was registered for this cause in 1867; and only nine have been registered in the last four years.

The rate of mortality from urinary calculi in New York may now be stated as being three deaths annually in 1,000,000 inhabitants, or as 129 deaths in 1,000,000 of all that die. In England the rate is seven deaths in 1,000,000 living, or 367 deaths in 1,000,000 of all that die.

It may be that the introduction of the clear Croton water has contributed no small share to this favorable result in New York.

FUNERAL OF SIR JAMES Y. SIMPSON.—At the funeral of this renowned man, celebrated May 13th, the procession numbered upwards of 1700 persons, and 70 carriages followed.

DEATH OF A DISTINGUISHED WESTERN SURGEON.—Dr. Chas. A. Pope, of St. Louis, Mo., and well known throughout this country, committed suicide in Paris on July 5th.

CHARLES SUTHERLAND, Lieutenant-Colonel and Brevet-

Colonel, Assistant Medical Purveyor, U. S. A., is in this city assuming (temporarily) the duties of Chief Medical Purveyor.

Rhode Island Medical Society.—The Fifty-ninth Annual Meeting of this society was held in Providence, June 8th, 1870. Dr. Alonzo Clark, of New York, was elected an honorary member.

The Trustees offer the following prizes for the year 1870:—First, *Ununited Fractures;* the conditions under which they occur, and the most successful method of treatment. Second, *Hydrate of Chloral;* its physiological effects and therapeutic uses.

For the best dissertation on each or either of these subjects, the Trustees will pay the sum of one hundred dollars. Essays must be sent to the Secretary of the Fiske Fund Trustees, Dr. S. A. Arnold, on or before the first day of May, 1871.

James Syme.—This distinguished Edinburgh surgeon died June 27, of paralysis.

A Venerable Medical Practitioner "across the Continent."—Dr. Jacob Bigelow, of Boston, Mass., æt. 84, recently left for San Francisco, Cal., by rail "to get rested."

Cultivation of Cinchona in India.—The cinchona tree is successfully produced in Madras and Bengal. The number of plants at Darjeeling, on an area of 905 acres, exceeds 3,000,000, the increase during the past year being 673,654. The tallest plants were 19 feet high.

University of Prague.—Dr. Hering, of Vienna, has received an appointment to the Chair of Physiology in the University of Prague, formerly held by the late Prof. Purkinje.

Death of a well-known Medico-Legal Gentleman.—Francis B. Cutting, Esq., of New York City, who died on Sunday, June 26, 1870, æt. sixty-five, was at one time one of the most distinguished lawyers in this country.

Dr. Jacob Bigelow, of Boston, Mass.—This distinguished medical man was elected April 6th, 1870, a Corresponding Member of the Medico-Chirurgical Society of Edinburgh.

New York City Physicians.—There are 1594 registered physicians, in good standing, in New York City.

Liestenschneider.—Wm. Liestenschneider, of Collinsville, Ct., was relieved a few days since of a tapeworm thirty feet long; almost as long as his name.

Death of Lady Simpson.—The widow of the late Sir James Y. Simpson died at Killin, Perthshire, Scotland, June 17th.

Prostitution in London.—From the latest advices there are one hundred thousand well-known prostitutes in the city of London.

University of Edinburgh.—Dr. Alexander Simpson, nephew of the late Sir James Y. Simpson, has been elected to the Chair of Midwifery in the University of Edinburgh.

Soap.—The earliest mention of soap is made by Pliny, who declares it to be the invention of the Gauls. The Latin word *sapo*, from which we get our word soap, is said by Beckmann to be derived from the German. Both hard and soft soaps were in use among the Germans; and Pliny describes not only the mode of manufacture from tallow and ashes, but the use of soap as a medicine.

The New York Medical Journal Association.—The Trustees of this prosperous Association have authorized the Librarian, Dr. A. E. M. Purdy, to bind the most valuable sets of American and foreign medical journals which have been accumulating during the last six years.

The majority of the working members of the medical profession of New York City—old and young—are members of this organization, which, although young, is already a rival of the older medical societies.

The regular Friday evening reunions ended with the month of June, but the Secretary, Dr. F. A. Burrall, informs us that there will be an occasional meeting during the hot months, and the members will be notified as usual by the Librarian. The stated reunions will recommence in October.

Manhattan Eye and Ear Hospital.—This Hospital was opened in its temporary location, 233 E. 34th street, New York, October 19, 1869. *Surgeons*—Drs. C. R. Agnew, E. G. Loring, Jr., and D. B. St. John Roosa. *Clinical Assistants*—Drs. O. D. Pomeroy, T. R. Sturgis, and C. J. Pardee. *House Surgeon*—S. B. St. John. Open daily for the poor at 2 P.M.

Abernethy's Dislike to Unnecessary Talk.—People who came to consult this eccentric man took care not to offend him by bootless prating. A lady on one occasion entered his consulting room, and put before him an injured finger, without saying a word. In silence Abernethy dressed the wound, when instantly and silently the lady put the usual fee on the table, and retired. In a few days she called again, and offered her finger for inspection. "Better?" asked the surgeon. "Better," answered the lady, speaking to him for the first time. Not another word followed during the rest of the interview. Three or four similar visits were made, at the last of which the patient held out her finger free from bandages and perfectly healed. "Well?" was Abernethy's monosyllabic inquiry. "Well," was the lady's equally brief answer. "Upon my soul, madam," exclaimed the delighted surgeon, "*you are the most rational woman I ever met with.*"—*Jeaffreson's Book About Doctors.*

Novel Anatomical Preparations in the Museum of the Royal College of Surgeons, London.—Martin Van Buchell's first wife, embalmed by William Hunter; the intestines of Napoleon, showing the progress of the disease which was eventually fatal to him; and the forearms (preserved in alcohol) of Thomas Beaufort, third son of John of Gaunt, Duke of Lancaster.

The Author of Mesmerism.—Mesmer in one year received in Paris 400,000 francs in fees. He died in obscurity on the 5th of March, in the year 1815.

Arsenic Eating in Styria.—The question of the notorious immunity enjoyed by the Styrian arsenic-eaters against the otherwise so fatal effects of that poison has lately been investigated by Dr. Weber, of Freiburg. He first applied himself to find out why the primary symptom of gastritis, which is the first observed when any quantity of arsenic is taken, should be absent in them. Now he finds that the Styrians always take the white arsenic in substance, either alone or with bread or bacon, once or twice a week, and only at the new and full moon. They generally begin with one-eighth or one-fourth part of a grain, and go on with this dose until they find it no longer sufficient to produce bracing effects. They then gradually increase it, and it is only years after having first commenced the use of the arsenic that they are able to take quantities

varying from three to six grains, which to persons unaccustomed to the mineral would be a fatal dose. That no gastritis follows, Professor Weber ascribes to the small initial dose, and the exceedingly gradual increase which takes place. The initial dose causes no inflammation, but only irritation, which, if frequently repeated, leads to thickening of the mucous membrane, and more especially of its epithelial layer, whereby the membrane is effectually protected from a too profound action of the poison. It is, therefore, not surprising that at last doses are easily borne which would produce gastritis in other persons, just as habitual drunkards may, with a certain amount of impunity, take pure alcohol, which would cauterize the stomach of others.—*Medical Mirror.*

Celibacy in Women.—Dr. Maudsley, in his third lecture at the College of Physicians, says:—"Sexual hallucinations, betraying an ovarian or uterine excitement, might almost be described as the characteristic feature of the insanity of old maids, the false visions of unreal indulgence being engendered probably in the same way as visions of banquets occur in the dreams of starving persons, or as visions of cooling streams to one who is perishing of thirst. It seems to be the fact that, although women bear sexual excesses better than men, they suffer more than men do from the entire deprivation of sexual intercourse." This may be quite true, but, of course, it is rather difficult to prove it. Many persons connected with asylums have told us that male epileptics are more frequently thus affected from masturbation than females; and how does Dr. Maudsley know that celibates don't masturbate?

A New Method of Preventing Lead Poisoning.—A communication on this subject has recently been read to the Paris Academy of Medicine from the director of one of the principal glass manufactories in France. In the establishment minium is prepared in large quantity, and, in spite of every precaution, the workmen infallibly succumbed to lead poisoning in a longer or shorter period. Two workmen only, who had been in the habit of drinking a quantity of milk every day, escaped the disease. This fact attracted the attention of the director, who put all the workmen in the place on similar diet. From that time, February, 1868, not a single case of colic has been observed.

Galvanic Amputation.—M. Sédillot recently amputated the penis by means of galvano-cautery. The operation lasted five minutes, and the patient made an excellent recovery.

Post-Mortem Elevation of Temperature.—Few physicians are aware that so far back as the year 1770 the celebrated physician De Haën, of Vienna, observed that an elevation in the temperature of the body occurred in the death-agony, and persisted for some time after death had actually taken place. The observation, however, was soon forgotten, and it is only recently, since attention has been especially directed to the changes occurring in the temperature of the body in disease, that the fact has been re-established. The point has been made the subject of a prize by the University of Berne, and the prize has been carried off by M. Valentin, a relative, we believe, of the well-known physiologist. The following are the principal results at which he has arrived: The development of heat after death is common to all bodies, though varying in degree in different instances. As soon as the development of heat in the body after death is greater than the coetaneous loss of heat by physical causes, an increase in the temperature occurs. This occurs, consequently, either from an increase in the development of heat, or from the concurrence of circumstances diminishing the loss of heat. The post-mortem elevation of temperature primarily results from the persistence of the vital processes which ordinarily lead to the development of animal heat, even after the heart has ceased to beat. Augmentation of these processes, which especially result from certain nervous influences, may cause great post-mortem elevation. The occurrence of rigor mortis, although causing the elimination of some heat, is yet only of subordinate influence on the general elevation of temperature that occurs after death. It is not improbable that post-mortem disintegration and decomposition may to some extent aid in the post-mortem elevation of temperature. The loss of heat after death is, *cæteris paribus*, much smaller than during life, owing to the cessation of respiration, and the diminished evaporation from the skin; and this may also be accessory to an elevation of temperature without the actual generation of heat. The experiments which enabled M. Valentin to draw the foregoing conclusions were made on the dog, rabbit, pig, guinea-pig, marmot, pigeon, and frog.—*Lancet.*

Parchment Paper.—To convert paper into vegetable parchment, immerse it for a few seconds in a cold mixture of one volume water and two volumes sulphuric acid. Wash out rapidly by plunging in a large quantity of cold water, and finally remove all traces of the acid by further immersion in water to which a small quantity of ammonia has been added. To prevent the tendency to contract when drying, it should be attached to a frame while wet, or allow it to dry under a press. Paper prepared in this way is very transparent, and can be used for copying by tracing. It is extensively employed as a substitute for parchment made from sheepskin in diplomas, certificates, patents, and for envelopes.—*Chemical News.*

Retracted Nipple.—Dr. Geo. H. Lyman, Boston, Mass. (*Boston Med. and Surg. Journal*), at a late meeting of the Boston Obstetrical Society, described the manner in which the child's tongue "strips" the nipple between its tongue and upper jaw, as a milker strips the cow's udder with his fingers. He had observed the operation in the mouth of an infant with hare-lip.

He had also related the case of a woman whose nipple was so poorly developed as to be apparently on a level with the breast. After confinement the breast could not be evacuated; the consequence of which was an excessively troublesome abscess. In her next pregnancy the plan was adopted of breaking off the neck of an ordinary wine-bottle (with smooth lips), and binding it on to the breast in such a manner that the circular rim of glass pressed upon the areola around the base of the nipple. This was done for ten days preceding confinement, and the result was most satisfactory. Not only was a deep circular depression made around the nipple, but the latter became more elevated; and the success of the experiment was established by the ease with which the child, when born, accomplished the act of sucking.

Tincture of Gelseminum.—A case of traumatic tetanus relieved by tincture of gelseminum is reported by Dr. Thomas Smith, of Savannah, Ga., in the *Baltimore Medical Journal.*

Spasmodic Stenoses.—Hamburger, of Vienna (*Boston Med. and Surg. Journal*), in his "Clinical Researches upon Diseases of the Œsophagus," under the name *spasmodic stenoses*, describes two forms of spasmodic contraction—*stenosis spastica migrans* and *stenosis spastica fixa.*

Original Lectures.

LECTURES
ON
THE PALSIES
AND
KINDRED DISORDERS OF THE NERVOUS SYSTEM

By MEREDITH CLYMER, M.D.

Lecture IV.

SHAKING PALSY.

General Physiognomy of—Definition—Confounded with other disorders—First described by Parkinson, 1817—Clinical History and Prognosis—Mechanism of Tremor—Causes and Pathogeny—Pathogeny of Tremor—Differential Diagnosis—Treatment. (Three Illustrations.)

You have all probably seen a person somewhat past middle life, yet looking much older than his years, hurrying along with a singular hopping walk, stepping on the toes or fore part of the feet, his trunk bowed forwards, his head bent on the chest or thrust out in a peculiar way, his semi-flexed arms brought closely to the sides, with the hands clasped and pressed against the belly, or if apart, trembling very much, the saliva trickling from the corners of the half-opened mouth, with look agape, and an expression of senile imbecility. If you see such an one attempt to sit down, it will be done with difficulty, as if the joints were stiffened and the act painful, and when done the hands and feet, if not supported, and sometimes the head, will at once set shaking. Such is the physiognomy of the curious nervous disorder called *Shaking Palsy*, or *Paralysis Agitans*, and which will be the subject of this lecture. It may be defined as a neurosis, usually of gradual and insidious onset and unknown cause, though occasionally of sudden seizure and rapid evolution after some moral emotion, as fear, for example; its chief and initial symptom is incessant trembling of one or more limbs, the arms being most commonly first affected; this is accompanied or soon followed by more or less muscular weakness in the shaking limbs; a special feature of its developed stage is a precipitate shuffling or trotting gait; slowly progressive in its course; and ending, if unchecked, in well-marked palsy and general debility, under which the sufferer sinks; and having, so far as we know, no anatomical characters.

The term Shaking Palsy has been always very loosely used; it has been given to many disorders in which tremor is a prominent symptom, but which pathogenetically are not akin, such as some forms of chorea, senile trembling, the tremulous affections of muscles in children, and the tremor caused by certain metallic poisons, as lead, mercury, etc.; and until quite recently it has been constantly confounded with a disease with which it has much in common, but from which it essentially differs in both its clinical and pathological facts, namely, *multiple* or *disseminated cerebro-spinal sclerosis.*

Having to deal in these lectures more with clinical than chronological histories, I shall not detain you by inquiring whether this malady was known to the ancients, or if when Sauvages described his scelotyrbe festinans he meant paralysis agitans,—and if he did he curiously omitted from the account any mention of the chief symptom trembling,—but will tell you that the first separate, intelligible description of shaking palsy was by Mr. Parkinson, in an essay published in London, in 1817, and it has been adopted and copied since by all the systematic writers. Although Parkinson's delineation is both accurate and graphic, he having seen quite a number of patients with the disorder, yet he confounded the neurosis with the organic disease, and this has been done by all the English, and American, and German writers who have followed him. To the French belongs the credit of having differentiated the two diseases, and established a distinct clinical and pathological species of disseminated cerebro-spinal sclerosis.* To those who have had the good fortune to follow Dr. Charcot's teachings at the Salpêtrière Hospital, frequent opportunities have of late years been given of seeing both the clinical and anatomical demonstrations of this important fact; but the first public announcement was in Dr. Ordenstein's thesis, of 1867, and in the published lectures of Dr. Charcot during the following year, 1868.

As I have already remarked, the beginning of this disorder is, in most cases, of such gradual approach that few patients can fix the precise time. Slight muscular weakness or heaviness, generally in a hand or forearm, sometimes bilateral, with a tendency to tremor in the limb on excitement or after exertion, are the first symptoms which attract notice. At the same time, or in a little while, some stiffness in the affected muscles is usually complained of. These symptoms may remain months or years thus limited in degree or extent, or be only shared by the muscles of the lower jaw; I have known the tremor to be for a time only occasional, and for cause, as when the patient is put out about anything, or attempts to lift a heavy weight, or carries a cup or tumbler to the mouth, or extends fully the forearm on the hand, or catches a catarrh; though in most cases there is very gradual but very certain progress both in intensity and the parts involved. But there are many instances in which the seizure was sudden, after some great fright, and the tremor was generalized almost at once. One of Charcot's cases was instantly taken in the street with cramp in the toes of the right foot, which lasted for five minutes. Immediately following this the foot began to tremble, and in five or six months the whole of the right side was affected, and before long the tremor extended to the left side. This patient, a woman, had, however, before the seizure, been subject to fits of trembling when abused by her husband, of whom she was in constant terror. These cases are exceptions, and I shall have occasion to refer again to them when I speak of the causes of this affection. Let us suppose, then, that the first troubles are, as in a case I lately saw, in the right arm, and that heaviness and a tired feeling after use have been complained of, soon followed by constant trembling; after a little while the right leg is attacked, and then the left arm, and not long afterwards the left leg. In other words, the tremor becomes general so far as regards the muscles of the extremities, and occasionally of the head. Sometimes an upper and lower limb of the same side are seized at the beginning, and we have the hemiplegic, or unilateral, variety of the disorder; or the tremor may be in the arm and leg of opposite sides, forming the crossed form of the disease.

Before proceeding further let us study the special mechanism of this prominent symptom, tremor; and first, as it happens in the hands, which we will suppose

* See on this subject, Notes on the Physiology and Pathology of the Nervous System, with Reference to Clinical Medicine. Part I. Disseminated Sclerosis of the Brain and Spinal Cord. By Meredith Clymer, M.D. New York, 1870.

to be in pronation. We have a series of oscillations, constant, quick, equal, and regular, which not only carry the hand from side to side but also in a continuous movement of attempted flexion and extension, so that, to adopt Dr. Charcot's description, the projection of the oscillations is not rectilinear but a sort of elongated oval curve; the forearms being semi-flexed, the effect is very much like the action of a person who is beating a drum. Now as these movements take place in all the articulations of the limb, and with alternately slight flexion and extension in the articulations of the fingers, wrist, and elbow, there is an incessant tendency in the hand to open and close, and when the patient attempts to press the hand of another person the sensation is given of a series of hurried shocks. Sometimes, particularly where the hand is alone or chiefly interested, the thumb moves on the other fingers, as if in the act of rolling a pencil; otherwhile the rhythmic motions of the fingers are of a more complex coördinating kind, as if engaged in crumbling bread. In the lower limbs it is very much the same. The centre of motion for the foot is the tibio-tarsal joint. If the patient is lying down this constant movement of extension and flexion is very manifest, and may continue even when he is standing up, and he beats time with musical precision with his feet. When in the horizontal position the knees in some cases are in constant ab- and ad-duction, often striking against, and bruising each other, and causing excoriations. The head, obedient to the action of the muscles of the neck, wags or nods, or, what is more common, executes a movement between these two, with partial rotation. The tremors may be stayed for a short time by the will or during sleep, or from the effects of chloroform, or by placing the limb against a resisting surface. Intercurrent disorders have caused their temporary suspension, as an attack of hemiplegia, but they return as the palsy disappears. They are increased by the slightest moral emotion, or by any physical effort, as taking hold of anything, rising from a seat, or setting out to walk. After the disease has lasted some time, it not unfrequently happens that the limbs become permanently deformed, and this is particularly the case with the hands, whose special distortions have been accurately described by Dr. Charcot. In the first degree, shown in this drawing (Fig. 1), the nearly extended

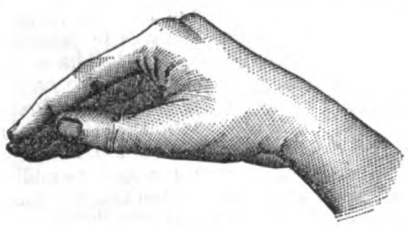

Fig. 1.

fingers are flexed on the metacarpals, and drawn towards the thumb, the position of the hand being much like that when holding a pen, or taking a pinch of snuff. In time this deformity becomes exaggerated; the distal phalanges of the fingers approach yet nearer towards the thumb, and are more contracted, and finish by being completely bent in on the palm, whilst the second phalanges are in a state of permanent over-extension, and the third are slightly flexed on the second (Figs. 2 and 3). This distortion of the hand resembles very much what happens in chronic articular rheumatism.

The tremor has a decided influence upon the volitional acts of the motory system of the affected members. For instance, whilst at the outset the patient is able to

Fig. 3.

execute certain movements which require considerable muscular effort, he is utterly incapable of doing any act where nicety and precision of muscular combination is necessary. He cannot write, or, if he attempts it, the scrawl he traces bears witness to the incoordination of the muscles of his hand; he is unable to button his clothes; he cannot seize a glass without probably upsetting it; and when he wishes to carry a cup or tumbler to his mouth, he is obliged to resort to a series of grotesque movements. Sometimes he will place the vessel on a table, and seize the rim with his lips, at the same time holding it firmly with both hands.

The peculiar gait I have already mentioned; the knees are somewhat flexed, the chin generally rests on the breast-bone, or the muscles of the neck may be on the stretch, giving a singular stiffness to the set of the head, the trunk is bent forwards, and in this way the subject goes stepping on his toes or the balls of the feet, at a rapid, almost uncontrollable pace, as if, to borrow Trousseau's expression, he were running after his centre of gravity. This capering, trotting pace is a necessity to maintain the equilibrium; there is a feeling of insecurity all the time, and a constant dread of falling over if the speed is slackened. Some patients seek the support of a wall or railing, and shuffle along close beside it, at times bearing their shoulders against it. Nearly always there is more or less difficulty in starting; once the balance is got, off they shoot. Dr. Graves tells of a gentleman who, when about to walk, was obliged to have himself balanced and set off by some other person, just like a piece of machinery. When once set agoing, and on a smooth road, he went very well for a while, but if the ground became uneven, or he reached a hill, he was irresistibly compelled to run backwards in a right line until stopped by some one. And this brings me to mention a phenomenon which many writers have regarded as characteristic of paralysis agitans, that is, the festination (scelotyrbe festinans of Sauvages), or irresistible impulse to go forward. Now I believe this singular phenomenon to be exceptional in shaking palsy; it certainly may exist independent of it. It should not be confounded with the instinctive "go a-head" feeling which I have just spoken of, and which keeps the patient going because he fears to fall down if he stops or slows, just as it is

safest to ride a stumbling horse with whip and spur. But in festination the patient is urged forward by an impulse he cannot resist, as in Sauvages' case, where he could not turn to the right or to the left till he brought himself against an obstacle, supported by which he would turn his body gradually round and then hurry straight on again. In this case there is no mention of tremors. Other instances are related, and Romberg gives several in which the propulsion was backwards, as in Dr. Graves's case when he was stopped by an acclivity, and he makes it a variety, paralysis agitans retrograda. In one of Dr. Charcot's patients there was a tendency to fall backwards, and Dr. Ordenstein mentions having seen but once festination in a patient in Dr. Guillot's wards. When speaking of the pathogeny of this disorder, I shall have occasion to recur to this curious phenomenon.

The motor troubles, which I have just hastily analysed, are the essential, distinctive features of shaking palsy. The modifications of sensibility, cutaneous and other, are uncertain; most generally tactile sensibility remains natural. Romberg speaks of darting pains, and Blasius of a peculiar painful feeling in the nape of the neck, which he regards as very characteristic. In the cases which I have seen, and those which I have analysed as the foundation of this lecture, these symptoms were wanting. Charcot has, however, signalized a subjective sensation which is often very annoying, namely, a constant feeling of heat or burning in the skin of the back, or over the epigastrim, though sometimes it is felt in the face and limbs. It may be at times so intense as to cause the patient to throw off the bed-clothes; and yet the thermometer shows no increase in the local body-heat. It is not at all times of the same intensity, but seems aggravated by the trembling fits; it may come on in spells, and then disappear for awhile. It is often accompanied with profuse sweating. I have never seen it in shaking palsy; but in two cases of nervous disease, where the lesions were probably in the pons and medulla oblongata, one of which is now under my care, this sensation of cutaneous heat in the back and breast has been very distressing; it is not, however, constant, but only occasional; in one case it was coincident with violent perspirations. The special senses are unaffected; the mental faculties are good (both relatively to age and existing complicating maladies); and the organic functions are, with these reservations, regularly performed. The pulse-rate and body-heat would seem to be, from the observations made at the Salpêtrière, unchanged.

Shaking palsy is a notably chronic affection, and in many cases does not seem to abridge life, lasting for thirty years and upwards. Maclachlan mentions one of the pensioners at Chelsea Hospital, then in his 107th year, and who had been affected since he was sixty years of age. But generally it is more or less regularly progressive, with occasional pauses. After five or six years the tremors become generalized; the muscles of the mouth and tongue are affected; the saliva constantly dribbles; speech is broken; mastication is hard, and sometimes swallowing; motility gradually lessens in the tremulous muscles, and they obey less and less the will; walking is increasingly difficult and finally impossible; and the sufferer is obliged to lie on his couch or bed shaking day and night, except during the occasional snatches of sleep, which are always uncertain and short; his comfortless existence is ended suddenly by some intercurrent disorder, most often pulmonary; or, worn out by want of rest, bad nourishment, incessant suffering, and bed-sores, he sinks slowly, the tremors sometimes stopping awhile before death.

There are no *anatomical characters* proper to paralysis agitans. Wherever such have been reported they have either been instances of the disease known as disseminated sclerosis of the brain and cord, and which I propose to call *cerebro-spinal sclerosic palsy*, or they have been mere coincident lesions, and not the anatomical expression of the affection. Accurate histological examinations have very recently been made of the morbid anatomy of this disease, and, as yet, without result.

The much-quoted case of Oppolzer is clearly one of sclerosis. Dr. Ordenstein has witnessed three autopsies. In the first, in which the disorder had lasted thirty-three years, there was attenuation of the nerve-tubes, and they were separated more than normally from each other. This of course means nothing, and conveys no idea, and had better been left unsaid. In the second there were softening of both cerebral peduncles, lesions of the medulla oblongata, etc., all accidental and not necessarily connected with the disease; and in the third the result was again negative. Ollivier and Charcot have been alike unsuccessful. Leubuscher mentions the case of a young woman who was seized with tremors of the head, arms, and muscles of the face, particularly those of the lips and tongue, difficulty in walking, with a disposition to fall over forward. After death a fibroid tumor was found occupying the whole thickness of the pons varolii. In Dr. G. E. Paget's case of "Involuntary tendency to fall precipitately forwards" (*Medical Times and Gazette*, vol. i., 1855), there was what I take to be a sclerosic patch in the central part of the right crus cerebri.

I have no doubt, as we become more skilled in our investigations of nerve-tissue, that material changes will be made out. So far we must be content to confess our ignorance and put shaking palsy amongst the neuroses.

Let me say a few words respecting the *pathogeny of tremor*, the initial, constant, pathognomonic feature of this palsy. We have first to understand the true signification of the term muscular tone, first used by Blasius to represent the state of permanent contraction of the fibrils when a muscle is apparently in a state of inaction, or is at rest, and by means of which the equilibrium between antagonist muscles is maintained. To explain this condition, some physio'ogists have imagined an inherent vital property of the fibre; "a hypothetical creation as useless as it is manifestly incorrect," justly observes Professor Vulpian. Others again have called in the aid of a special presiding centre of the spinal cord. Dr. Vulpian has analysed, and, I think, probably correctly interpreted, the condition in this way. He says, in his admirable lectures on "The General and Comparative Physiology of the Nervous System:" "Muscular tone is a reflex action, hence not only the intervention of the motor nerves is implied, but also that of the grey substance of the cord, and the sensory or excito-motory nerves. We must therefore suppose all these constantly active, and all our experiments satisfactorily show this to be so." Marey has proved by the myograph that muscular contraction consists of a series of waves, as it were, so quickly successive, that they seem to be continuous, and their break is only shown by analysis.* Now any interruption of this steady active force, de-

* "It is demonstrated then that in a normal (muscular) contraction the will sends to a muscle through the nerves a series of successive impulses, the degree of whose number, frequency, and intensity, constitute the contractions, weak or strong, short or long, according to the effect desired to be produced. The muscles therefore would be naturally the seat of rapid oscillations of the nervous agent, similar to those which so manifestly exist after poisoning by strychnine." (*Du Mouvement dans les fonctions de la vie*)

manding organic integrity of considerable range, is necessarily followed by imperfect function, or tremor. There is no excess of physiological action, no nervous irritability or over-stimulation, but always a diminution of power, a paresis or palsy, according to degree. And this answers completely the objection the late Dr. Trousseau made to calling this disorder a palsy, which he says has been very inappropriately so termed. It is very true that in the earlier stages a patient is able to make muscular efforts requiring considerable energy. If the affection is unilateral or confined to one limb, as an arm, the hand of the damaged side may squeeze the dynamometer with such force as to make it mark several pounds more than the sound hand can do. If the arm be flexed the patient may for a time resist your efforts to extend it against his will, and so on; but this state of things does not last. It is an unnatural expenditure of nerve-power and is soon exhausted. The hand that was opened and shut with seeming facility for some moments gradually ceases to work. This is the case in several other disorders of the nervous system, in which deficiency of muscular ability is conceded. Senile tremor, which in many respects is akin to paralysis agitans, unquestionably goes along with loss of muscular vigor. In old persons a little over-exertion is followed by distressing fatigue, and often with trembling, and the movements become uncertain and jerking. No one certainly attributes this state to increased nervous power. Now in all these instances motor impulses continue to be sent from the centres to the muscles, but capriciously; the current is more or less interrupted; the producing centre works fitfully. Let at any moment some damage to one of the sensory centres happen, as a clot or an embolus, shown by sudden hemiplegia, and, as I have before said, the tremors cease, and gradually recur, as the secondary lesion is removed. This, I think, goes far to establish the correctness of this hypothesis, and it gets additional strength from those instances where tremor is a secondary phenomenon, as after cerebral softening, or tumors, or sclerosis of some of the brain centres.

If pathological anatomy has failed to fix any constant coarse lesion in simple paralysis agitans, it has shown us in cases where tremor was an intercurrent or secondary symptom, what part of the cerebral mass was diseased, and justifies us in making the guess that when its anatomical characters are made out their site will be found in the medulla oblongata, pons varolii, and cerebral peduncles, according to the range of symptoms and their degree.

Shaking palsy is emphatically a disease of advanced life. In five of Parkinson's cases the patients were all over fifty, and the average age was above sixty. Out of a large number of cases among the inmates of Chelsea Hospital, not one was below fifty-five, and the majority were between sixty-five and seventy. Trousseau says that he has seen it in middle life, and once at twenty-seven years of age. I think it most probable that where it has been reported as occurring in young persons the diagnosis has been faulty, and some material lesion of the nervous centres, in which trembling was a conspicuous symptom, has been set down as a case of shaking palsy. In 30 cases analyzed by Ordenstein, 6 were between 30 and 40, 9 between 40 and 50, 5 between 50 and 60, and 10 between 60 and 70. Parkinson, Maclachlan, and others, consider it as unquestionably almost wholly a disorder peculiar to males. The statistics of the Salpêtrière Hospital show this to be an error; and I have certainly seen it as frequently in females as in males. An examination amongst the inmates of our almshouses will, I believe, prove this statement to be correct. Habits of life would seem to have no productive influence; not so, I think, with respect to heredity; a careful analysis of a number of cases will, I believe, show that often several in a family are sufferers. Some authors mention its having been preceded by chronic rheumatism; but when we consider the number of persons past fifty who are thus afflicted and yet escape paralysis agitans, we must have more relative proof to establish the connection. There is more evidence of the influence of wet and damp. In a case reported by Dr. Gull, a man, forty-four years of age, passed the night in wet clothes, and was seized four days afterwards. Romberg tells us of a German who was stripped of his clothes by the Cossacks whilst in a sweat, and left naked on the damp ground for some hours, and who was attacked a few days subsequently; but here there was probably the concomitant factor fear. Dr. Chéron reports the case of a baker, who returning to his lodging, over-heated and perspiring, walked half-an-hour in a drenching rain; he was immediately taken with pains and cramps in his left shoulder, and two months later was seized with tremor in the same arm.

The effects of emotional disturbances, as sudden fright, are unquestionable. Among other authenticated instances, there was for many years in the Salpêtrière Hospital a woman, the wife of a mounted Paris policeman, who, during the early part of Louis Philippe's reign (1832), saw her husband's horse come back riderless to the barracks, and, supposing him killed, at once had a violent fit of trembling, which continued as shaking palsy; she died of the disease in 1865. Dr. Chéron gives two cases where it came on in an arm, on learning unexpectedly a sudden loss of fortune. Dr. Gull has related an instance of paralysis agitans, confined to the right arm, which followed a blow received on the arm four or five months previously. A nervous female, forty years of age, subject to hemicrania and supra-orbitar neuralgia, after a diarrhœa lasting for some months, which reduced her to a state of great debility, had her left leg begin to tremble, and the right was soon afterwards seized, and then the arms. The list of fifteen different causes given by Sanders, in his article in Reynolds' System of Medicine, is trifling and unworthy serious consideration.

The *differential diagnosis* of shaking palsy and senile trembling, and the various toxic tremors, alcoholic, lead, mercurial, &c., I shall more particularly point out when I come to treat of these disorders as a class. As regards disseminated sclerosis of the brain and cord—cerebro-spinal sclerosic palsy—between which and paralysis agitans there exists much clinical kinship, and so much confusion, I shall at this time only refer you to the abstract-table on the board, promising to enlarge upon this subject when we take up together the study of this latter affection.

SHAKING PALSY.	CEREBRO-SPINAL SCLEROSIC PALSY.
Formative stage uncertain, and marked by no constant symptoms; sometimes rheumatoid pains, formication, weight in one or more upper limbs.	Nearly always initial symptoms; almost constantly weakness or heaviness in lower limbs, with vertigo, hemicrania, &c.
Tremor an initial symptom, and constant except during sleep.	Tremor follows paresis, is never initial, and occurs only when provoked by a voluntary movement, and absent at all other times.
Frequently characteristic permanent deformities of the hand.	Late in the disease when the palsy is well-marked, permanent rigidity of the

SHAKING PALSY.	CEREBRO-SPINAL SCLEROSIC PALSY.
	affected limbs, sometimes alternating with chronic spasms (spinal epilepsy).
In most cases no proper tremors of the head, the shaking of the head being communicated by the convulsive movements of the body.	Often tremor of the head when unsupported.
No nystagmus.	Often nystagmus.
Speech broken and interrupted, syllables bounced out.	Speech slow, each syllable pro-noun-ced; scanned as it were.
No spasmodic muscular snatches.	Frequent muscular snatches.
Gait characteristic, and attitude of body peculiar.	Gait and attitude those of a paraplegic.

I will not detain you in speaking of the *treatment* of shaking palsy by cataloguing a list of remedies which have all been found wanting. But we have a means which has in many instances appeared to secure a perfect and permanent cure, and in others to have afforded decided relief for a shorter or longer time. I mean the constant galvanic current. Ten years ago the late Professor Remak published in his work on Galvanotherapy a case of paralysis agitans cured by the constant current, and several cases where the improvement was more or less marked and durable. At this time the therapeutic effects of the constant current had been but little studied, they were imperfectly understood, and Remak's theories and statements were not in good odor. Since his death, with better knowledge of the remedial powers of galvanism, and the absence of personal antagonism, his truthfulness and the correctness of most of his views have come to be generally owned. Many cases of cure or bettering of this heretofore intractable disorder by Remak's treatment have since been published. Dr. Russell Reynolds has reported a case in a man of fifty-six years of age, well-marked though recent, in which after five applications of Pulvermacher's chain (continuous current) of 120 links, daily for one hour, the tremors ceased, and in a month, with an application every second day, the cure was complete. Quite recently Dr. Jules Chéron, of Paris, has had out of seven cases treated by the constant current, two complete cures, two where the improvement was very marked, and which at the time of his report were still under treatment with every prospect of ultimate success, and three in which the general condition of the patients was bettered, but where there was no change in the degree of tremor. Benedikt's success, as stated in his work on Electrotherapeutics, is about the same. I should say from a careful analysis of the cases I have collected treated in this way, and from my own more limited experience with it, that if a happy result is to be hoped for it must be in recent cases, before the tremor becomes generalized, and while it is still limited to one or two limbs. If you try this method in the cases seen in our incurable hospitals and poorhouses, which are of long standing, you may, almost certainly will, for a time improve the general health and make the sufferer's condition more tolerable, but you will fail to exercise much if any controlling or durable influence on the tremor. Do not try faradism; it is at best worthless, and most often hurtful. I should mention that Dr. Axenfeld, of Paris, reports the case of a man, æt. 53, with the developed disease, in whom all the symptoms were suspended for eighteen months, by the simultaneous use of iodide of potassium, sulphur baths, and cauteries to the neck.

The tremors may be temporarily controlled by subcutaneous injections of morphia and atropia combined, and the daily sufferings of a patient worn out by the ceaseless muscular snatches much alleviated. Professor Edward H. Clarke, of Boston, has lately tried in a case of ten years' standing the chloral hydrat, and with good effect. He says the man would lie shaking for an hour or two after getting to bed before going to sleep; that during the three months he had been taking chloral—40 to 60 grs. in divided doses every night—he has slept peacefully for eight hours. It had no effect on the tremors during the day, but it secured him for a third of the twenty-four hours.

But whether we use galvanism or not, be the case recent or of long continuance, do not neglect a general restorative treatment. It is the underlying therapeutic principle in the treatment of all these chronic nervous disorders. Not borne in mind, all specific methods will be more or less failures. In most cases of shaking palsy the general nutrition is bad. Premature senile decay marks this and kindred disorders; old age is discounted; and we must try to regenerate and reconstruct tissue more or less devitalized.

ANTIPHLOGISTIC TREATMENT IN DISEASES OF CHILDREN:

REMARKS BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION, APRIL 15 AND 22, AND MAY 27, 1870.

By A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Lecture I. Part II.

[Continued from p. 101.]

With these introductory considerations, Mr. President, I come to speak of the principal remedies which are known by the name of antiphlogistics; and I shall first direct attention to

DEPLETION.

Both local and general depletion play an important part in medicine of olden times. They were prominent amongst the antifebriles and antiphlogistics. Of more modern writers, Peter Frank relies in feverish diseases on rest, spare diet, and depletion; Reil and Hufeland confine its indication to genuine inflammatory fevers; Schönlein resorts to it where there is too much reaction on irritation, for its two effects, viz., first, for its diminution of the amount of blood, and secondly for its alteration of the blood. Canstatt depletes for the purpose of counteracting, not the reaction, but the effects it will work on the organs; Traube resorts to depletion before he expects a crisis to take place, hoping for a considerable fall of temperature; and Virchow states that this reduction of the febrile temperature will take place although it be but temporary.

It was early noticed that a depletion, especially a general one, was followed by great changes in the condition of the blood. About the time of Broussais and Bouillaud, the inflammatory character of the blood was considered to be in the fibrine; inflammation consisted in the prevalence of fibrine. They found that the blood, after repeated depletions, would, when studied in the basin, and after cake and serum had separated, exhibit increasing amounts of fibrine. Instead of a warning, this observation proved a new inducement for further depletion. Their grave mistake ought to ren-

der us careful in selecting a remedy which is more than doubtful. We ought not to forget that blood ought to be as normal as possible, if expected to perform its functions in both physiological and pathological organs. Besides, clinical experience shows that blood when getting thin, that is, when containing more than its ordinary amount of water, gives rise—partly from its diluted condition, and partly from deteriorated nutrition of the trophic nerves and the walls of the blood-vessels—to effusions and extravasations. Thus local or general dropsy is the result of a number of debilitating diseases. Swelled face or feet, menorrhagia, and epistaxis are common consequences of general anæmia, or rather hydræmia, and may be cured by beef, iron, and fresh air.

In anæmic children every inflammatory disease leads to serious dangers in short time, and on slight occasion. A rapid pneumonic infiltration in a convalescent or debilitated child is of daily occurrence. After a diarrhœa leading to hydræmia, or during a diarrhœa complicated with an inflammatory affection of the lungs, the danger from this disease is greatly increased. Children are, besides, more subject to hydræmia than adults. For the latter have but to reproduce the elements of their bodies; the child has both to reproduce and to steadily increase. Thus a lack or waste of material is badly felt. Unless you save as much material as you possibly can during the progress of a disease, convalescence will be protracted, incomplete, or interrupted. I have seen many a case of inflammatory disease in children taken hold of with the whole antiphlogistic armament of the school. While the disease was getting starved out, the patient perished with exhaustion or convulsions. The latter are in many cases the results either of directly debilitating treatment or of insufficient nutrition; hydrocephaloid conditions are known to follow diarrhœa or any other affection resulting in organic losses. In fact, most of the brain diseases of infancy and childhood are of a secondary character; primary genuine inflammatory affections are very rare indeed. A very frequent form of encephalitis in the new-born and very young, when at all suspected or recognized, consists in a rapid disintegration of the nerve tissue, and therefore contra-indicates depletion at once. Another frequent form of cerebral affection, tubercular meningitis, is never a primary disease, but always a part of universal tuberculosis. I need hardly add that scarcely ever in these diseases will there be a justifiable indication for blood-letting; and still, just where you expect it least, depletion is frequently resorted to. In a large number of instances I have found leeches applied to the heads of patients suffering from tubercular meningitis, when the pulse was rising beyond 140 or 160 or more, and their temperature was up to 106° or 107°. This condition takes place, and is almost universally found, in the very last stage of the disease; in reality, the symptoms enumerated are those of the last stage—of rapidly increasing paralysis. I take it for granted that a patient with these symptoms will die in from 60 to 72 hours after the rise of temperature and pulse I have mentioned; and need not state that invariably a depletion will render the patient worse, and accelerate dissolution. I am afraid that a good many leeches are still applied more to soothe the attendants than to benefit the patient. Still, if we know that we can do no good, and shall probably do harm by such treatment, we ought to insist upon the public's learning that they cannot pull the stars from the heavens.

The greatest danger arising in the course of inflammatory diseases of childhood and infancy is from exhaustion. This condition, and collapse, will occur frequently where we least expect it; thus, for instance, after protracted cold applications. In this latter case we can remove the cause instantly by withdrawing the application, and the patient may speedily revive; but in collapse from depletion, we cannot so readily remove the cause, and can hardly hope for such speedy recovery from imminent danger. In pneumonia the dangers are various. In its progress the complication with intestinal catarrh is not very uncommon; it is a disagreeable condition, no matter whether it is accidental or the result of mechanical stasis in the ramifications of the portal venous system. At the same time the nature of the disease, abstinence from food, and now and then the treatment also, will rarefy or impair the blood with all its consequences upon the tissues, and the dangers of a new infiltration.

After what I have said of the effect of blood-letting, both local and general, the question arises, are we justified in resorting to depletion at all? Now, it is an established fact, or at least a very general conviction, that when we perform venesection—for the relief of pneumonia or meningitis, for example—we do not relieve the pneumonia or the meningitis itself, but we do relieve the collateral œdema which has taken place in the tissues as yet uninvaded, or but partially invaded, by the inflammation. And by this relief of the collateral congestion and œdema, say of the meninges or of the brain, we may save a patient from approaching dissolution. Such cases are rare; but when they occur, when we have to deal with acute œdema, we must of course resort to depletion in many a case. I recall a case of convulsions where I myself opened the jugular vein. I did not know the cause of the convulsion, but the venous congestion was so evident and so extreme, that I was led to relieve it as soon as possible. I think Trousseau relates a similar case. We know that the immediate danger in such cases depends not upon the primary cause of the affection, but upon the prolonged congestion, which may give rise to effusion or extravasation. To avert these I do not object to venesection—indeed, it may become imperative.

But to depletion as a general antiphlogistic, I must object, and this whether it be made by venesection or by local blood-letting. I know that there is great difference of opinion on this point, and those who disagree with me may do so upon good grounds. Yet that even leeching is often attended with grave dangers, a case which came under my notice will suffice to show. A child with some inflammatory affection and high fever had leeches applied, and the part left under a warm fomentation. At his next visit the physician was told that the fever was entirely gone, and the patient sleeping well. But on seeing the child he found it with a blanched, waxen face, and in collapse—a state of things readily explained on opening the clothing, which was saturated with blood. The patient recovered, and the doctor was *naïve* enough to attribute the recovery to the accident of the profuse hæmorrhage. I know that we often hear of plethora, of surplus of blood; if such a condition ever occurs, it is certainly not in infancy. At that period any surplus would be sure to be used to build up the body, to contribute to growth.

In full accordance with the remarks you have been so kind as to receive to-night, I shall add as a practical contribution, which is but the result of my theoretical convictions and some clinical experience, that I seldom resort to depletion in inflammatory diseases of infancy and childhood. I do not remember a case of pneumonia in which I have applied leeches, for many years. Nor do I believe that my statistics have been impaired by my sparing blood. Meningeal and cerebral affections are, at least with us, mostly of a seconda-

ry character, and seldom require direct depletion. They sometimes do, I feel sure; but generally I think, wherever extensive derivation is really indicated, the immense surface of the mucous membrane of the intestinal tract, not to speak of skin and kidneys, appears of greater importance and promising of more effect, than a local depletion about the head. After all, the general principles laid down by Johannes Munster as early as 1604, appear to be correct even in our times. Clinical observation had done for his judgment, as it did for Galenus's, what has been obtained in our times by improved methods of examination and observation, and sounder theoretical reasoning. His opinion concerning blood-letting in children is, as usual in those olden times, fully given in the title of his book, which I here present: "Joannis Munsteri, Philosophi ac Medici Heilbronnensis, Disputationum περὶ παιδορλεβοτομίας Libri V. Quibus saluberrimum Galeni, Medicorum Principis, decretum De non mittendo pueris infra XIV. annum sanguine, pro Alexandro Massaria Vicentino, adversus Horatii Augenii à Monte, sancto virulentas in eo argumenti genere calumnias, enormiaque sophismata, defenditur. Typis Cellianis. Anno 1604."

COLD.

The medical use of cold in feverish and inflammatory diseases is by no means of quite recent date. The first authority who is generally credited with its extensive administration for the purpose of reducing the increased temperature is Currie (Medical Reports on the Effects of Water, Cold and Warm, in Fever and other Diseases, 1797), whose opinions on the indications in the treatment of fever are clearly indicated in the following sentence: "Though I am far from thinking that fever consists merely of a series of phenomena originated in a morbid accumulation of heat in the system, yet this symptom evidently occurs more or less early in that disease." After Currie, the cold-water treatment disappeared for some time, in consequence of the public prejudice, but modern experience and experiments have installed it again into its rights. Reil, already, knew the double effect it had, in both cooling and stimulating; Kolbany, Horn, and Fröhlich appreciated it; and Gietl used it extensively, in 1843, in a typhus epidemic raging at Munich. Brand, Ziemssen, Bartels, Jürgensen, Liebermeister, and Küchenmeister have since enriched the literature with, in part, excellent monographs on the subject, especially with regard to the use of cold water in typhoid and typhus fevers; and the literatures of other countries are gradually following the lead of the Germans on this topic.

At this opportunity I should not omit to credit an older author than any of them, with what is due to his memory. I do not remember to have met with an allusion to his writings. I refer to: "*A Letter from Dr. Glass to Dr. Baker, on the means of procuring a distinct and favourable kind of small-pox, and on the use of cold air and cold water in putrid fevers.* London, 1767." On p. 32 sq. of his pamphlet, Dr. Glass has the following:

Hot stimulating medicines, cold air, and cold water, properly used together, are the most effectual means to compel the heart, arteries, and fibres to exert their utmost force; and these have been very successfully used in malignant fevers, attended with excessive lowness and faintness. At Gombron, according to Sir John Chardin's account, the extremely hot, close, and suffocating air produces dysenteries and malignant fevers, that prevent this place from being inhabited for one-half of the year. "Sir John Chardin himself was seized in the night with a violent fever, three days after he left Gombron, and grew delirious within a few hours. The next and following days he had such fainting-fits that all who saw him in them, thought him actually dying . . . . . On the fifth day treatment was commenced, while a French surgeon, whom Sir John had with him, thought he had no chance of recovering. . . . At nine o'clock the apothecaries' servant brought the medicines that were ordered, and staid to administer them. The first thing he gave him was near a pint of emulsion, made with the cooling seeds; and soon upon it, an incredible quantity of a cordial confection, that contained all kinds of antidotes; and some time after, about a quart of a nauseous, bitter, purging liquor; and as soon as this was got down, so much of the cordial confection as he took at first. These medicines, which were taken within the space of an hour, soon increased his heat and thirst to an intolerable degree. His attendant then told him he might drink as much, and as often as he pleased, and mixing for him barley-water and willow-water in a large china bowl, and putting a large bit of snow into it, he gave him the bowl when the snow was almost dissolved, that the liquor might be drank as cold as possible; and he supplied him with this exceeding cold and pleasant liquor as often as he had an inclination to drink, which was very frequently, during the whole time his fever lasted. The bed on which he lay was placed on the ground, in a large airy hall, the floor of which was every now and then plentifully sprinkled with cold water, so that it stood in pools all over the room. But his fever still increasing, the apothecary directed him to be taken out of bed, and laid on a mat with nothing at all to cover him but his shirt, and at the same time employed two servants to fan him without intermission. All this, however, made but little or no alteration, for his heat seemed to be as intense as ever. Two large buckets of fresh cold water were then ordered to be brought, the patient was set on a chair, and supported by a servant on each side, whilst his apothecary poured the cold water on his thighs, legs, and feet, beginning at the upper part of the thighs, and proceeding gradually to the extremities. After this, he poured cold rosewater on his head, face, neck, arms and breast."

Sir John instantly improved, but next day the fever returned, though in a milder form. A similar treatment was resorted to, and Sir John lived to tell his own story. Dr. Glass then goes on saying, p. 37:

This uncommon and surprising practice so effectually employed in curing a burning fever, accompanied with excessive weakness and faintness, in a very hot, sultry climate, may possibly, if duly considered, point out to us a more successful method of treating our putrid malignant fever than that which is at present most commonly used. . . . Our most prudent and experienced physicians, in order to avoid opposite errors, content themselves with prescribing mild cordial diaphoretic medicines. But then nature is almost left to struggle by herself against a very violent disease, having but little assistance from art, either against the putrifying heat, or intolerable faintness. Whereas, by imitating the Persian method, a physician will have it in his power to command the feverish heat, and may restrain and lessen it, and, even though increased by hot cordial medicines, to what degree he thinks proper. . . . Hence it appears that such cold applications, carried no farther than to keep the feverish heat within due bounds, concur and co-operate with hot stimulating medicines in increasing the power, action, and force of the heart and the other vital parts.

On p. 42 we read the following:

Such practitioners as are prejudiced in favor of the common method, and believe that the only safe way of treating malignant fevers is to keep the patient, if possible, in a gentle breathing sweat until the disease is carried off by it, will probably be surprised to find anything proposed in favor of an empirical practice, that shuts up all the pores of the skin at once, and totally stops the evacuation which they are so solicitous to encourage and promote. But it is certain the most rational of the Greek physicians, in order to extinguish the intense heat of ardent fevers, when they were at their height, had recourse to cold water. Of this they sometimes gave very large and frequent draughts, and sometimes they plunged the patient into it. It is, however, true, that they always expected a profuse and critical sweat would suc-

ceed; and it was to answer this intention that Hancock likewise gave cold water in fevers.

But some years since, as Professor Cyrillus informs us, a new method of using cold water in acute malignant and destructive fevers was introduced by the Neapolitan physicians, which is this: As soon as the dangerous symptoms appear in the advanced state of the disease, the patient, after fasting some hours, must drink every hour, or once in two or three hours, a pint or two of water cooled with snow. . . . If there should be at any time an appearance of sweat, it must be immediately suppressed, by making the water that is to be drank, colder, and giving it in a larger quantity; by uncovering the patient and exposing him to a current of cold air, and by fanning him. Nay, some have gone so far as to sprinkle snow itself powdered on his skin. . . . See Philosoph. Trans., No. 410. Abridg. by Eames and Martyn, vol. viii., part iii., p. 655.

Relating the experience of Dr. Brocklesby, in his *Medical Observations*, p. 66, concerning the favorable course malignant fevers took in cold and exposed sheds, while the rest of the soldiers lying sick in better quarters did very much worse, our author adds, p. 49:

In all the barns, cottages, and rooms belonging to the castle, which were closer and provided with fires, it may be taken for granted that the air was kept at least moderately warm, since it is the opinion of all persons who are employed in attending and nursing the sick that the pores of the skin ought to be kept open in all fevers, and in all other acute distempers. But the keen cold wind of the forest having a free passage through the openings left between the boards of the shed, the sick lodged in it must necessarily have been exposed to extraordinary cold. Now, as warm air and very cold air are so powerful and contrary agents, it is reasonable to conclude they must have produced very different effects on the sick, and the event was that in all the hospitals where the air was warm, remarkably more died than in the shed where the air was very cold, though treated exactly in the same manner in every other respect. Hence it seems that the amazing salutary effects of the latter were owing to extraordinary cold air.

From the preceding facts and observations may we not venture to infer that it is not enough for patients who are sinking in putrid fevers to have the air they breathe continually renewed, for this is done in rooms that are kept warm or hot by a constant fire; but that we ought to procure for them a current of cold air, which may, together with the assistance of other means, effectually cool, refresh, and strengthen them, especially when great danger is apprehended from lowness and faintness with heat. And we have, I think, good reason to expect more success in pursuing this method, ... than by going on in the more beaten track. . . . .

Thus, clothed in the scientific language of the last century, Dr. Glass arrives at a number of practical conclusions of great importance. It is not his fault, nor that of those who proclaimed the same truths, that they have been forgotten, denied, or proscribed.

The beneficial influence of cold air is aptly alluded to. If ever there was a murderous weapon in the hands of both physicians and public, it was the heat of the sick-room. The prejudiced opinion that the disease could or must be eliminated through the skin, gave rise to the close and heated temperature in which patients suffering from inflammatory, or typhoid, or eruptive fevers, were broiled before they could perish *lege artis*. Cold, in the shape of cold or cool air, will come under the head of simple dietetic agents; in the shape of cold water, or ice, it may be classed among the remedies proper.

Having thus briefly referred to the history of the employment of cold as an antiphlogistic, I may, at our next meeting, be permitted to offer some clinical observations upon the subject.

Original Communications.

TRISMUS NASCENTIUM.

By JAMES S. BAILEY, M.D.,

ALBANY, NEW YORK.

This disease is generally fatal, and seldom seen in this climate. Only three cases occurred in this city during the year 1868, in a population of about 80,000 inhabitants.

They were as follows:—

Case I.—Dr. C. D. Moscher was called to assist a midwife in a protracted case of confinement. The patient was a stout, robust German woman, and had been in labor four days, during which time she had lost a large quantity of blood. On examination he found the presentation natural. There was partial placenta prævia, a portion of the placenta being detached and resting between the head and the pelvis. The doctor immediately turned and delivered; in doing so, he was compelled to use considerable force. The child nursed, and seemed well until the 8th day, when symptoms of trismus commenced—the spasms increasing in severity and frequency as the disease progressed.

The jaws were never entirely closed, the end of the little finger could at any time be introduced between them, but it required force to separate them beyond a certain point. Opisthotonos was well marked. The cord separated upon the 6th day, and the umbilicus had a healthy appearance. The child died upon the 15th day.

Case II.—Mrs. M——, an Irish woman, was delivered by a midwife of a large girl child, which seemed quite promising until it was seized with trismus upon the evening of the 9th day. The first symptoms observed were, the child refused to nurse, moaned, and seemed languid, being in a disturbed sleep most of the time. The pathognomonic symptoms became well marked during the second day. The stools were frequent, and of a dark greenish color. The eyes remained partially open, and its hands were tightly clinched upon the thumbs. The cord fell off upon the 5th day. The navel looked raw and inflamed and tumefied, was scarcely healed when the child died upon the 17th day. There was very much emaciation. Two days before its death its right side was quite cold, and its back presented a livid hue.

Case III.—My brother, Dr. Wm. H. Bailey, invited me to visit with him a well-developed male mulatto infant which seemed in every respect healthy until the 5th day, when its mother observed it was exceedingly nervous, starting at the least touch or noise, refused to nurse, and seemed drowsy. The next morning there were contortions of its mouth, with foaming mucus exuding. Upon examining its jaws they were found to be locked. The spasms were aggravated by trying to nurse it. The symptoms were fully developed in the course of twenty-four hours. During the paroxysms there was extreme lividity of countenance, and it seemed as if the eyes would be forced from their sockets. The cord separated upon the 7th day. The umbilicus remained dry and inflamed, without suppuration. Its bowels were regular, and the stools were natural in appearance. Death took place upon the 9th day. No post-mortem was allowed in either case.

The causes assigned for trismus are various. In certain localities malaria is supposed to be a strong predisposing cause; badly ventilated apartments and lack of cleanliness are supposed by others to act thus. Many

attribute it to irritation and inflammation of the navel. My observations on several hundred cases, treated in the Southern States, have convinced me that neglect and mismanagement of the umbilicus is a strong exciting cause, and that in consequence a traumatic condition has been established.

The history of the foregoing cases amply establishes this fact. In Dr. Moscher's case, although at death the navel seemed healthy, according to his statement, during the delivery there must have been some dragging upon the cord, perhaps producing some rent or tear at its junction with the abdominal integuments, for trismus was developed about the time we should expect it from local injury. The loss of blood may in this case have aided somewhat by enfeebling its constitution, and thereby leaving it less power to resist this morbid influence.

In Case II. there was inflammation and tumefaction of the umbilicus. Case III. also gives a faithful representation of the condition of a wound about the time traumatic tetanus is developed. Vitiated atmosphere and want of cleanliness in these cases could not be considered as producing it, for the apartments were cleanly and well ventilated, and in this city we are free from vegetable miasm.

Progress of Medical Science.

CHAMBERS' LADDER OF MEAT-DIET FOR INVALIDS.—Dr. Thomas King Chambers, of London, publishes in his valuable work on "Indigestions" the following meat-diet for the sick:—

Whey; milk and lime-water; milk and water; plain milk; milk and sago; milky rice pudding; beef tea; plain mutton broth or chicken broth; Scotch broth; turtle soup; sweetbread (the thymus gland of the calf); boiled fish, especially water souchy; boiled partridge or boiled chicken; mutton chop, grilled in the air, and without fat; roast joint of mutton.

Roast joint of mutton is the Promised Land of the convalescent; when he arrives at that it is a matter of time and strengthening the stomach by occasional tonics, for him to come to the digestion of anything within the scope of his birthright. And even if he has to stop at roast joint of mutton, he will stop at a very good thing.

RECIPE FOR PREPARING BEEF-TEA AND SOUP FOR THE SICK.—Make the cook understand that the virtue of beef tea is to contain all the contents and flavors of lean beef in a dilute form; and its vices are to be sticky and strong, and to set in too hard a jelly when cold.

When she understands this, let her take half a pound of fresh-killed beef for every pint of tea she wants, and carefully remove all fat, sinew, veins, and bone. Let it be cut up into pieces under an inch square, and set to soak for twelve hours in one-third of the water required to be made into tea. Then let it be taken out, and simmered for three hours in the remaining two-thirds of water, the quantity lost by evaporation being replaced from time to time. The boiling liquor is then to be poured on the cold liquors in which the meat was soaked. The solid meat is to be dried, pounded in a mortar, and minced so as to cut up all strings in it, and mixed with the liquid.

When the beef-tea is made daily, it is convenient to use one day's boiled meat for the next day's tea, as thus it has time to dry and is easiest pounded.

Some persons find it more palatable for a clove of garlic being rubbed on the spoon with which the whole is stirred. I prefer a bit of celery heated in it. Good soup is that which is most like this beef-tea, and is a very digestible article; bad soup that which least resembles it, is to be avoided as poison.—*Chambers on "Indigestion."*

POISONING BY BINIODIDE OF MERCURY.—M. K. Taytor, M. D., Asst. Surgeon U. S. A., Fort Gratiot, Mich. (*The Boston Med. and Surg. Journal*), alludes to a case of poisoning by biniodide of mercury, and as this drug is becoming a popular remedy in the treatment of diseases of syphilitic origin, and mistakes are liable to occur, it would seem necessary that toxicologists should give this subject a more thorough investigation, and indicate to the profession some additional means of counteracting its baneful effects. So far as his means of judging goes, the employment of liquor potassæ, solutions of carb. potassa, extemporaneously prepared, lime-water followed immediately by bicarb-potassa, and the sulphide of ammonia or potassa, the latter being the better (as it can be administered in doses of five or six grains, largely diluted, with safety), followed by emetics or the stomach pump, constitute the chief antidotes.

The extreme rarity of casualties of this kind—no cases being reported, according to the leading works on medical jurisprudence—has led to neglect on the part of the toxicologists and chemists in determining more explicitly, in varying emergencies, the best course to pursue in the treatment.

CATHETER IN THE BLADDER IN PLASTIC OPERATIONS.—Prof. G. Simon (*Deutsche Klinik*) finds in plastic operation on the urinary or sexual organs, that it is unnecessary to leave a catheter in the bladder so long as the urine is acid, whilst such operations should not be performed, if possible, when the reaction is alkaline.

THE POWER OF ELECTRICITY.—According to M. Sedillot, a current of electricity passed through red-hot platina wires or plates cuts through tissues as easily as a bistoury.

SHOULDER PRESENTATION—VERSION IN THE POSITION ON THE KNEES AND BREAST.—Dr. A. W. Lueck, of Mayville, Wis. (*The Med. and Surg. Reporter*), was called in a case of labor, to a German woman, multipara, aged 35, with her sixth child, who, while performing her household duties, was suddenly confined. On examination, the left hand of the child was found reaching out of the vulva as far as it possibly could; the face of the child was in the right iliac fossa, and the shoulder-joint far down in the lower strait. The contractions of the uterus were very strong. Although the liquor amnii had been drained for nearly 24 hours, and the uterus had forcibly contracted for over 12 hours, he first tried version in the usual position; the patient on her back, at the edge of the bed. But the child was so wedged in between the bones of the pelvis, that it was impossible to introduce his hand into the cavity of the uterus. Remembering the suggestions of Dr. C. C. Hildreth, (*Am. Jour. Med. Sciences*, April, 1866), he changed the position of the patient into that of the breast and knees, and was surprised to find how easily the hand was introduced and the child lifted out of the pelvis. The uterus was wrapped around the child as tightly as a bandage around a broken limb, but the turning was accomplished, and the child delivered dead.

The patient stood the operation well, but when it ended she became cold and almost pulseless. Stimulants were liberally administered, but it was not till after five hours that reaction took place. He repented not having given her an anæsthetic before version; the shock would have been less, and the operation might perhaps have been facilitated by it (that is, if the uterus relaxes

under the influence of an anæsthetic). For Dr. Lueck this case had another point of interest. Before commencing any obstetrical operation, he always ascertains how long since the bladder and rectum have been emptied. In this case the enquiry was made, and the answer was:—"I have just passed water a little before you arrived." This was taken for "legal tender"—which he ought not to have done—and did not introduce the catheter. While turning, the bladder was emptied of about six ounces of urine. He now thought of nothing less than of having caused a rupture of the organ. The patient is now well and perfectly sound. This occurrence has impressed the operator so deeply, that he will never trust the statement of a patient.

THE PHYSIOLOGICAL ACTION OF PROTOXIDE OF NITROGEN.—It has been a disputed point ever since the protoxide of nitrogen came into use as an anæsthetic, whether its action depends upon oxidation or whether the carbonic acid generated either by the ordinary disintegration of tissue, or by super-oxidation, produces the anæsthesia.

Dr. John J. Colton, of Philadelphia, Pa. (*Med. and Surg. Reporter*), having administered this gas to many thousands of persons, having inhaled it in his own person hundreds of times during as many successive days, and having carefully watched its effects upon the system under the greatest variety of circumstances and conditions, maintains that its action must depend upon oxidation, and that the indications of asphyxia (slight in ordinary cases) are merely an incidental effect rather than the main cause of the anæsthesia.

He publishes experiments which tend to establish this theory.

A UTERINE POLYPUS OF EIGHTEEN YEARS' GROWTH SUCCESSFULLY REMOVED.—J. W. Brooks, M.D., Chicago, Ill. (*The Chicago Med. Journal*), recently successfully removed an immense uterine polypus, which presented at the vulva, from a married woman, æt. 52. The dimensions of this amorphous polypus, after the blood was removed, were as follows: Circumference below the constriction, 12 inches; circumference at the constriction, 9 inches; above the constriction, 18 inches; circumference, longitudinally, more than 20 inches. Weight, after the removal of the blood, one pound ten ounces. Estimated weight of blood removed, four ounces. The structure was strictly fibrous. The lady is now in perfect health.

CASE OF OVARIOTOMY—PERFECT RECOVERY.—John H. Tate, M.D., of Cincinnati, Ohio (*The Cin. Med. Repertory*), reports the successful removal of a multilocular ovarian tumor, weighing 35lbs., from the right iliac region of a widow aged 56 years. She believes the tumor to have been occasioned by a caustic injection into the womb, which was given her by a surgeon for the cure of leucorrhœa. The patient is in fine health and spirits, and has not been so well for ten years.

OPIUM IN DIABETES.—Dr. Roberts Bartholow, of Cincinnati, Ohio (*Cin. Med. Repertory*), remarks, if diabetes be a disease of the cerebro-spinal nervous system, the first element of which is a dilatation of the arteries, and the second, alterations in the perivascular areas, it is obvious that the most appropriate remedies are those which have a selective action upon this part of the organism. Hence the utility of opium and bromide of potassium in diabetes.

Opium, one of the old remedies in diabetes, has lately been strongly urged upon the profession by Dr. Pavy, who reports a number of instances of its efficacy. In view of what Dr. Pavy has brought forward in its favor, and of his own observation, Dr. B. regards opium as a remedy of the first importance in diabetes.

VOMITING IN PHTHISIS.—A very common form of vomiting in phthisis is that which occurs during the evacuation of a large cavity. Various means have been employed to mitigate these symptoms without material benefit. The subjoined formula is recommended by A. P. Dutcher, M.D. (*Cin. Med. Repertory*): ℞ Acid. carboliæ (cryst.), gr. iv.; glycerine, tinct. cinnamon, ää ℥ j. M. Sig.—A teaspoonful every 4 hours.

A NEW TREATMENT OF TYPHOID FEVER.—Dr. T. C. Henry, of Cincinnati, Ohio (*Cin. Med. Repertory*), glances at a paper on a new treatment of typhoid fever, presented to the Royal Academy of Sciences of Lisbon, by Dr. Lucien Papillaud, of Lisbon, and publishes the author's management of this fever: Bronchial catarrh, which takes the form of bronchial pneumonia, is almost a constant symptom in this affection. Lesions of the respiratory passages are quite as important as those of the digestive passages. Bronchial catarrh appears entitled to have a part in the medication of typhoid fever, and the remedy is met in the sulphur and mineral waters. The medication consists in making the patient drink in proportion to his thirst, and without fixed dose, alternately, a ferruginous or sulphuretted water, and alimentation beside, regulated to his appetite. The effect of these waters is to restore innervation and nutrition, and repair the dynamic losses caused by the disease.

The carbonated ferruginous waters are almost all arsenical. Reasoning from the favorable action of the ferruginous water, Prof. Papillaud was induced to adopt, early in the disease, minute doses of arsenical preparation, in doses of two millegrammes to one centigramme, and it seemed to exert a happy influence, diminished the intensity of the febrile movement, and in an appreciable manner sustaining nutrition. The notion of pathogenic fermentation as the cause of infectious diseases is becoming more general.

Prof. Papillaud states that out of eighty cases he has lost but three, and that it has been his usual mode of treatment for years. He advises the employment of sponging the body of the patient with acid water, and all the other hygienical measures of the day.

CATHETERISM OF THE LARYNX.—Dr. Weinlechner, of Vienna, considers catheterism of the larynx, next to tracheotomy, the safest and most rational resort in cases of imminent suffocation during croup and diphtheritis.

CONSTIPATION.—Professor Samuel G. Armor, M.D. (*American Practitioner*), in a conversation with his friend, Dr. J. H. Baxter, of the United States Army, was informed that the extract of stramonium is beneficial in cases of constipation.

Prof. Armor has been in the habit of using belladonna in the form of suppository, in constipation; but following the suggestion of Dr. Baxter, tried the extract of stramonium in the same way, and is pleased with the results. It possesses, in his judgment, valuable alterative properties, which commend its use in many cases of constipation, independently of its action on the bowels. Half or three-fourths of a grain of extract of stramonium may be combined with sufficient quantity of cocoa-butter, made into suppository, and used by the patient each night on going to bed. It is admirably adapted in this form to obstinate constipation of nervous females, who suffer at the same time from pelvic irritations from various causes.

It quiets irritation of the uterus and bladder, calms

and soothes the nervous system, allays irritative actions generally, and permits the patient to sleep.

To give permanency, however, to its effects, its use may be accompanied or followed by small doses of nux vomica, or a dinner-pill composed of aloes and nux vomica. Universal and permanent tonic action of the paralyzed muscles of organic life is secured, and the morbid condition of the intestinal glands at the same time corrected.

Ergot of Rye as a Hæmostatic.—Dr. Curran (*Med. Press. and Circ.*) is favorably impressed with the action of ergot, in hemorrhagic cases of typhoid fever. In a case published by him, one full dose of ergot entirely averted the hemorrhage.

Hydrate of Chloral in Cancer.—Mr. Weeden Cooke, Surgeon to the Cancer Hospital, London (*Med. Press. and Circular*), is in the habit of administering hydrate of chloral in the different varieties of cancer, for the purpose of entirely relieving the patient from pain. As a night-draught, he has found 20 grs. sufficient.

But when pain is persistent the 10 gr. dose, three times daily, gives the greatest satisfaction. Squire's method of administration is recommended, viz., the addition of syrup of tolu and peppermint water.

A New Treatment for Burns.—M. Joel, of the Children's Hospital, Lausanne, finds that a tepid bath, containing a couple of pinches of sulphate of iron, gives immediate relief to young children, who have been extensively burned. In a case of a child four years old, a bath repeated twice a day—twenty minutes each bath—the suppuration decreased, lost its odor, and the little sufferer was soon convalescent.

A writer in the *Gazette Médicale* says that a piece of vegetable charcoal laid on a burn soothes the pain, and if kept applied for an hour cures it completely.—*Med. and Surg. Reporter.*

Infantile Mortality.—From a little work on "Infantile Diseases," by Dr. Selby Norton, we learn that in England there is no excessive mortality between the ages of four and five; under one year, the number of deaths forms a quarter of the whole annual mortality of England.

Administration of Brandy before Chloroform.—James Shaw, A. A. Surgeon U. S. A. (*Med. and Surg. Reporter*), writes as follows: "In all cases of surgical operations, I would agree with Dr. Stone, of New Orleans, La. Give a little brandy and water some fifteen or twenty minutes before administering chloroform, as a matter of safety in keeping up the heart's action."

Temperature of New-Born Children.—Prof. Andral believes that the temperature of new-born children is lower than that of adults only during the first half-hour after birth.

Spermatorrhœa.—Dr. C. W. Davis, Indianola, Iowa (*Med. and Surg. Reporter*), had a case of this character, in an old bachelor, who had used a great quantity of bromide of potassium, but found it *enervating*. He advised him to use bromide of ammonium, which is *innervating*, and an excellent calmative on the cerebro-spinal system. One drachm of bromide of ammonium was dissolved in 4 oz. of peppermint-water, and a tablespoonful twice a day was given before eating, to prevent the forming of bromide of starch, which is inert—as a large quantity of our ingesta is more or less composed of amylaceous matter. He also gave him pills composed of:

℞. Strychniæ, gr. ij.
Ext. Hyoscyami, 3j.
M. Ft. pil. No. 50. One pill before each meal.

This treatment was rapidly successful.

Normal Position of the Uterus.—Anteflexion in a varying degree is the physiological condition of the uterus in nearly half of all women.

A Case of Tubular Pregnancy.—W. C. Hunt, M.D., Chicago, Ill. (*Chicago Med. Journal*), publishes a case of tubular pregnancy in a young married woman, who had hemorrhage from the uterus, at intervals of from three days to a week, from Nov. 12th, 1869, until the 14th of January, 1870, when she died.

The autopsy, thirty hours after death, revealed the following facts: The right Fallopian tube contained a fœtus of three months' growth. The placenta attached at or near the junction of the tube with the uterus—a portion of its attachment had separated, and from this the fatal hemorrhage had occurred, rupturing the distended walls of the tube and escaping into the abdominal cavity. This attachment of the placenta was the source of the frequent hemorrhages from the uterus during the last two months. The cavity of the abdomen was filled with two and a half gallons of blood.

The uterus and appendages taken from the above case may be seen in the museum of the Rush Medical College, in Chicago.

Biliary Calculi.—A writer in *The Chicago Medical Journal* extols the use of olive oil in large doses for the expulsion of biliary calculi. He gave a pint of oil to one of his patients, and at the expiration of twenty-four hours more than one hundred biliary calculi passed per anum, more than sufficient in bulk to fill a half-pint measure.

M. Amussat's Lithotomy Forceps.—This surgeon has had forceps constructed the branches of which, when in the bladder, may be brought to a right angle with the handles, so as to seize hold of the stone in the fundus. The mechanism consists mainly in a rack worked at the junction of the branches.

A Case of Congenital Malformation.—R. K. Clark, M.D., South Hero, Vt. (*Boston Med. and Surg. Journal*), reports the subjoined case of malformation:—A boy, aged five years, residing in South Hero, Vt., has only a thumb and third finger, on the right hand, which is cleft to the wrist-joint. He has good use of these, and can pick up a pin or any small article as readily as a child with a natural hand. On the left hand there is a thumb and three fingers; the second finger, with its metacarpal bone, is wanting, and this hand, like the right, is cleft to the carpus, and has the appearance of having been removed by a surgeon.

The lower limbs of the child are normal to the knees. On the right there appear to be two knee-joints, one nearly in its normal position; the other, and the one to which the leg is attached, is on the inner condyle of the femur. Each has a patella. The bones of this leg are rather shorter than normal, and the lower extremity of the tibia is prominent and blunt, with no external malleolus. On the side of the fibula, about one and a half inch from the end of the tibia, is a foot, with its plantar surface towards the knee; on this foot the great toe is united to the next toe. Of course, this leg is worse than useless to the child. The left leg is normal to the foot, where the deformity of talipes varus exists. The child's general health is good, and mentally he appears brighter than most children of his age.

The Position of the Uterus.—This important organ has its correct physiological position, which is exactly

perpendicular to the floor of the pelvis, only in a third of women.

Osteophytes.—In 1850, Follin (*Arch. Gén. de Méd.*) called attention to the presence of osteophytes in the pelves of women who had died in childbirth.

Death from a Uterine Injection.—Dr. J. C. Nott, of New York (*New York Med. Journal*), informs us that Scanzoni published a case of death, in one hour and three quarters, from injecting carbonic acid into the cavity of the neck.

Sub-periosteal Resection.—Dr. W. R. Whitehead, of New York (*New York Med. Jour.*), in his "Remarks on Reproduction of Bone," alludes to a portion of rib reproduced by sub-periosteal resection by Prof. James R. Wood, of this city, who unites a large clinical experience of this subject with a rare ability for observation. This operation was performed for the first time by the Russian surgeon Karawayew, in 1839, and a little later by Textor.

Verneuil's Periosteal Resection.—A sub-capsulo-periosteal resection of the elbow-joint was first performed by Verneuil in 1859.

Black Hairs Turning White.—According to M. Brown-Séquard, black hairs turn white in from two to five days. He also believes that the hair, under peculiar circumstances, can turn white in a single night.

Dislocation of Hip-Joint of Ninety Days' Standing, Successfully Reduced.—Dr. H. H. Kimball, late House-Surgeon, Charity Hospital, N. Y., now of Minneapolis, Minn. (*North Western Med. and Surg. Jour.*), May 28th, 1870, successfully reduced a luxation of the hip-joint of 90 days' standing. The patient, a girl, æt. 10, was supposed by her parents to have had a disease of knee and hip joints. As soon as the child was completely etherized, Dr. K. proceeded to manipulate, adopting the usual method for this kind of luxation, the head of the bone being in the thyroid foramen.

The main point of interest in this case is the length of time that the dislocation had existed prior to reduction; the query naturally follows, whether or no the acetabulum is so filled that there will hereafter occur spontaneous luxation? The patient is still at rest and doing well. The joint is movable and symmetrical.

Carious Teeth a Cause of Disease.—Dr. P. G. Merry, of Stillwater, Minn. (*North-Western Med. and Surg. Journal*), contributes an interesting paper on this subject, and claims that in many cases of phthisis pulmonalis, dyspepsia, conjunctivitis, epilepsy, hysteria, uterine and rheumatic affections, and many other kindred diseases, we may trace their remote origin to a mouthful of carious teeth.

He strongly urges upon the practitioner the absolute importance of as thorough an examination of the teeth as he would make of the lungs, heart, or uterus, while attempting a diagnosis of any affection, whether acute or chronic, and should he find any disorder amongst them, send the patient *at once* to a reliable dentist, that they may be thoroughly overhauled, and the disease eradicated.

He alludes to three cases to corroborate his assertions.

Chronic Urethral Discharges.—F. N. Otis, M.D., N. Y. (*N. Y. Med. Journal*), in an article on "Chronic Urethral Discharges," gives us his treatment as follows: When, after a longer or shorter time, the acute symptoms of an attack of gonorrhœa have subsided, and there remains simply a purulent or muco-purulent, painless discharge, examination should be carefully instituted, with the view to ascertain the exact point to which the disease has extended, and, as nearly as possible, the pathological condition upon which the continuance of the discharge depends.

The indications for treatment are, to apply such local means as are most likely to diminish the excess of fluid, and to stimulate the membrane to a more complete performance of its functions. Solutions of the salts of zinc, lead, and iron, combining the astringent and stimulating properties in various degrees, are found well calculated to meet this double requirement. Vegetable tonics and astringents are found also of value. The more thoroughly the epithelial products in the discharges are degenerated, the more stimulating and astringent is the application required to be. When the discharge is not wholly without pain, he is accustomed to add 2 or 3 grains of the extract of belladonna to the following solution: Sulphate of zinc, or the acetate of lead, alone or in combination, and of a strength varying from one to three grains to the ounce of distilled water. When the discharge is small in quantity and chiefly mucous, the acetate of lead, grains *one* to *three;* the persulphate of iron, grains three to five; tannic acid, from five to ten, are often promptly efficacious.

He has seen positive benefit in quite a number of cases where a solution of two or three grains of phenol to the ounce of water has been used.

Catarrh of the Fallopian Tubes.—Hennig asserts that catarrh of the Fallopian tubes is more common than similar affections of the body, neck, or vagina. West also remarks that it seems doubtful whether affection of the Fallopian tubes does not play a far more important part than we have been accustomed to suppose, in the production of many of the ailments of the female sexual organs.—*N. Y. Med. Journal.*

Treatment of Typho-Enteric Fever.—Dr. A. Given, of Louisville, Ky. (*Chicago Medical Examiner*), for convenience of description, subdivides typhoid fever as follows:—Simple typhoid, typho-enteric, typho-cerebral, typho-gastric, typho-pneumonitis, and typho-malarial.

In the treatment of the typho-enteric variety, our especial attention must be directed to the pathological condition of that portion of the ilium occupied by Peyer's patches. The first effort should be to check ulceration of the intestines, and thereby prevent death by perforation. In order to accomplish this, the morbid secretion and action of the bowels must be arrested; for the constant passing of acrid secretions over the inflamed mucous membrane of the intestines increases the inflammation and hastens ulceration. By far the best agent now at our command is the turpentine emulsion made as follows: ℞. Oleum terebinth., ʒ ij; pulvis acaciæ, sacchar. albi, āā ʒ iij; Aquæ menth., ℥ ij; tinct. opii ʒ ij. Mix, and give a teaspoonful every 2 or 4 hours, until the bowels are checked; then lengthen out the dose to intervals of every 6 or 8 hours, until tenderness has subsided. The turpentine penetrates the ulcerated surfaces, corrects the morbid action, stimulates the tissues, and sets up the healing process. The tincture of opium is beneficial in arresting the peristaltic movement of the bowels, and allaying morbid irritability and susceptibility of the parts; and by its power of arresting secretion, it promotes resolution.

If the turpentine emulsion fails to check the ulcerative process, or disagrees with the patient, then, probably the next best agent that can be given is carbolic acid; from 2 to 4 drops may be administered in a teaspoonful of glycerine or olive oil, every 4 to 6 hours.

AMERICAN MEDICAL JOURNALISM.

It has often been asserted that American Medical Journalism is much below its deserved level, and that in usefulness and power it does not compare with the same calling in other countries. While we are willing to admit the truth of most of this, we still claim that, considering everything, we do not make such a contemptible show. Our periodicals as a whole are, in character of contents, much below what they should be; but we make the best of the circumstances under which we are placed. There is no excuse to be offered relating to the sparcity of our material for elaborate and exhaustive contributions, but to the difficulty in making them available to the profession. Our hospitals are large, numerous, and well conducted; but those whose duty it should be to work up the facts of experience and place them on record are culpably derelict. Upon such rests almost all the onus of the sin of omission. In this regard the profession of this country are so peculiar that the number of actual writers for the medical press is, comparatively speaking, very small. One of the explanations for this rests in the general low standard of education among us. While a great many who can write will not, a great many more who would write cannot. We have so often heard the avowal to the latter effect that we speak advisedly. Dr. N. S. Davis, of Chicago, in an address before the American Association of Medical Editors, thus refers to this point, and at the same time truthfully sets forth the difficulties which the editors of medical journals are so often called upon to overcome:—

"It is perfectly well known that a large part of those who enter upon the practice of medicine, under our system of medical education, are wholly destitute of that general education and mental discipline which is essential to the formation of a taste for reading and writing. Without an adequate knowledge of the elementary branches of common education, and without the slightest acquaintance with any of the sciences, they have performed the task of reading the text-books in medicine, much as the apprentice performs his task in a mechanic's shop; they have attended the heterogeneous courses of lectures in some medical college, during which they have made imperfect notes of as many formulas or prescriptions for particular diseases as they could, and they enter upon practice with full confidence that these formulas and their text-books furnish all the literature necessary for the rest of their lives. They have no taste for reading, and not the slightest appreciation of the value of medical periodicals.

"And if here and there one of this class is induced to patronize a journal or furnish a contribution, the letter is written in such style that the editor must either throw it into his basket of waste paper, and so far rewrite it, that the author would not recognize it as his, or let it appear in such condition as to disgrace the pages of his journal. It is directly to this imperfect education of the profession, that medical journalism owes both its limited patronage and the literary imperfections which have so frequently subjected it to disparaging criticism."

On the other hand there are a great many well-educated and capable practitioners who will not contribute to any journal, and whose whole time and energies are given to money-getting. This is another class peculiar to the American medical public, and who are in no small degree responsible for the character of the medical literature of the country. In no community is there a greater number of such men than with us, of whose actual existence their brethren would have sometimes reason to doubt. Very many of these are loudest in their criticisms of others who are trying to contribute their mites of experience to the common stock.

Still another cause of the low grade of American medical journalism is to be found in lack of editorial management. Too few of the fraternity devote to the office the amount of attention which the proper performance of the duties pertaining to it involve; with too many the mere notoriety which may attach itself to the name upon the journal is sufficient, while the only work that is done is that of revising the proof-sheets. The address of Prof. Davis, which by the way suggests the foregoing remarks, states this part of the case so truly that we cannot express our own convictions better than by quoting his words:—

"But, in our estimation, no part of our medical periodicals is more deficient than that which is expected to be filled by editorial matter proper. Some of them contain so little from the editorial pen, that their readers would hardly know that they were superintended by such a functionary, except as they see his name on the title-page. Others present one or two pages headed 'editorial,' and filled with facetious paragraphs, personal slurs, news items, and attention to new advertisements. Only a very few out of the whole number occupy what editorial space they have with candid articles, calculated to enlighten their readers on the many important questions connected with the sanitary, social, ethical, and educational in-

terests of the profession. And I think it may be said with truth, that in none of our periodicals do these topics receive the editorial attention that their importance demands.

"It is only through the periodical press that the great body of the profession can be reached. To sit in an editorial chair and occasionally growl at municipal authorities for neglecting sanitary measures; slur medical societies for imperfections in their action; indite facetious paragraphs about ethics; and ridicule the attempts of others to advance educational interests, is, to say the least, a very poor performance of the duties belonging to such a position."

Referring to the imperfect arrangements too often made by those intrusted with the editorial management of the periodical, he draws the following truthful picture:

"The members of the college faculty whose names have been put on as editors, or the ambitious young men whose names occupy that position, have provided no reliable corps of reporters to furnish what can be gleaned from the hospitals and medical societies, if any such exist in the neighborhood; they have no resources for original matter, except the voluntary contributions of members of the profession, and what is equally bad, they have no positive views of medical polity, medical education, or sanitary science, with which to give their own editorial space a positiveness and individuality calculated to attract attention and command respect. By personal solicitation, they succeed in obtaining contributions enough from their friends, to make a respectable show of original matter for the first few numbers; but this resource is soon exhausted, and they are obliged to increase their selections from other journals, to fill up the required number of pages; the fear of offending some interest, whose patronage is needed, deters from doing more in the editorial department than to write commendatory notices of books, or call attention to some new advertisement, until, heartily tired of the enterprise, they discover that they have not *sufficient time* to devote to the work, and either let it die, or induce some new man to undertake it, and go through the same process."

We present the foregoing remarks, and make the extracts, for the purpose of giving our readers an idea of the difficulties in the way of the real success of medical journalism, and the reasons why it does not take its deserved rank in this country. In so doing, we dare not consider our individual management of this periodical above reproach—it would be strange indeed if no criticism would be deserved,—strange if some one could not be found who could not complain of the policy of the journal and its general management; but we should be pained to think that any sin of omission, or of commission, was chargeable to the lack of an intention to do our best.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

ADJOURNED STATED MEETING, MAY 23, 1870.

DR. T. GAILLARD THOMAS, VICE-PRESIDENT, in the Chair.

INTRA-UTERINE MEDICATION.

DR. J. C. NOTT completed the reading of his elaborate essay on *Intra-uterine Medication*, the first part of which was presented at the meeting of April 18th. (See report on p. 183 of our current vol., No. 104.) He at first reviewed with considerable minuteness some points in the anatomy of the uterus, normal and morbid, in their bearing on certain dangers attendant upon intra-uterine applications. We mention a few of them, referring the reader to the paper itself in the *New York Med. Journal* for June. Not only is the mucous membrane of the uterus in immediate connection with its proper fibro-muscular tissue, but the follicles which stud it so closely have possibly an indirect communication with the uterine vessels. The vessels themselves are peculiar, the veins lacking an external coat, their internal being in contact with the uterine tissue; while the large capillaries of the mucous membrane lie very superficial, and in some cases may hang out loose, and nearly or quite bare of epithelium, into the uterine cavity. These conditions clearly afford the greatest possible facility for the absorption of matters, whether septic or medicinal; and, moreover, if the diminutive capacity of the cavity (normally nine to twelve minims) be not borne in mind, and a free return-channel secured, one may easily, even with a graduated syringe, inject fluid or air directly into the circulation through a ruptured vessel. The liability to this accident is of course greatest when, after parturition or dysmenorrhœa, the epithelium or even the entire mucous membrane has been thrown off, leaving the vessels more than usually exposed. This, and not the passage of fluid through the Fallopian tubes into the peritonæal cavity, is the most probable explanation of the violent symptoms which occasionally follow uterine injection. "The peritonæum has no such exquisite sensibility until it has had time to inflame."

That remedies applied within the uterus are very apt to be absorbed is seen in the fact, for example, that the acid nitrate of mercury so employed sometimes salivates within a few hours. If this salt, which at once destroys the tissues it touches, can thus be taken up into the system, much more readily may be a solution of nitrate of silver, for instance, which, though it precipitates albumen, does so in minute flocculi, the albuminate being soluble in a solution of alkaline chlorides, like the uterine secretions.

But there are some cases of violent symptoms attending intra-uterine applications not to be accounted for either by the direct or by the indirect entrance of substances into the circulation. For these we must assume a morbid sensibility of the uterus, like that of the vagina in vaginismus. The ætiology of yet other cases, perhaps the most frequent of all,—in which, a day or two, or a week or two after probing, cutting, or cauterizing the uterus, there is a development of metritis, perimetritis, salpingitis, ovaritis, or general pelvic peritonitis or cellulitis,—is still involved in great obscurity.

In conclusion, the speaker reverted to the position he had taken at the former meeting, that the most important thing in the treatment of endometritis is the fre-

quent cleansing of the membrane from its foul secretions, which else might remain and putrefy within the uterus—would be sure to do so in flexions, where the cavity is enlarged and the outlet narrowed or occluded. For this purpose copious injections must be used, either of water alone or of this impregnated with some solvent of albumen. (Muriatic acid would dissolve not only thick mucus, but even the blood-coagula of persulphate of iron.) To avoid, as far as possible, the risk attending uterine injections, the cervical canal must be dilated, by one means or other, sufficiently to admit a double canula of large size, like the one he had himself exhibited; and the tolerance of the uterus must be either ascertained or brought about, by beginning with the weakest solutions and proceeding very cautiously to stronger ones.

DR. PEASLEE.—In connection with Dr. Nott's previous paper, Mr. President, I expressed my appreciation of its great value and of the immense importance of the subject it discussed. I said that subject presented three questions, each of which demanded the most careful consideration—a consideration which, so far as the limited time would allow, they have received in the paper of to-night. These questions are: 1. In what conditions should intra-uterine medication be resorted to? 2. What applications should be made? 3. How should they be made? I will make a few remarks upon the last of the three.

In order to give my remarks more definiteness, let me revert, for a moment, to the changes in nomenclature which I proposed at the former meeting. The lining membrane of the body of the uterus we agreed to call the *endometrium;* the substance of its walls, the *metrium ;* and its investing membrane, the *perimetrium*, —whence we had *endometritis*, *metritis*, and *perimetritis*. In like manner, the lining membrane of the neck of the womb will be the *endotrachelium ;* the proper tissue of its walls, the *trachelium ;* and its investing membrane, the *peritrachelium*. Inflammation of these parts will be designated as *endotrachelitis*, *trachelitis*, and *peritrachelitis*. The word τράχηλος has already found place in our anatomy (in the musculus trachelo-mastoideus, for example), and we need these new derivatives from it to give precision to our discussions.

Intra-uterine applications are either endometrial or endotrachelial. Dr. Nott has spoken only of the former, of applications to the cavity of the body of the uterus; but those to the canal of the cervix are fully as important, if less difficult to make; and it is often quite as essential to separate the two in practice as to distinguish them in theory. I show here a set of instruments both for endometrial and for endotrachelial medication, which I have been using for a considerable time. It comprises, first, the means of dilating the cervix; secondly, the means of keeping up the dilatation *ab libitum*, for hours or days; and, thirdly, the means of making applications to the lining membrane of the cervix or of the body. These I have devised in order to insure certainty and safety in the use of such applications; for I do not hesitate to say that, hitherto, endometrial applications have been made very much at random, and with uncertain results. If we can now be sure of applying to the endometrium just as much or as little of a medicament as we please, and be sure that any overplus will find ready escape, we have made a material advance.

In the first place, we must, of course, dilate the cervical canal, for the reasons so clearly assigned by Dr. Nott. This is usually effected by the sponge tent, and if the cervix be very firm, that is unquestionably the best means; but if it be in an easily dilatable condition, the dilatation can be completed within half an hour by the set of steel dilators, five in number, which I here present. The largest of them has a diameter of about three-eighths of an inch, and where this size cannot be passed, no endometrial injection should ever be thought of. At a meeting of the Obstetrical Society six or seven years ago, Dr. Kammerer and I found that we had both been experimenting independently upon dilators, and each had been using his own instruments for a year or more, ignorant of the other's. The chief peculiarity of mine lies in a bulb placed an inch and three-quarters from the extremity, so as to prevent unnecessary interference with the endometrium.

The cervical canal dilated, we wish to keep it so while we make our applications; and for this purpose, as well as to limit the applications to the part intended, whether the endometrium or the endotrachelium, I have here three little canulæ, or intra-uterine specula, if you choose.

No. 1, for endometrial injection, is a silver tube, three-eighths of an inch in diameter, and two inches long, having a collar at its vaginal extremity, with an eye for attaching a thread; three fenestræ, side by side, each half an inch long and one-fifth the circumference of the tube, commence an inch and a quarter from this extremity; above the fenestræ the tube tapers, like a Minié ball, to a very small opening directed toward the fundus. You observe that the fenestræ begin so high up that the endotrachelium is completely protected from the action of any fluid injected. It is my view, however, first, that injections, unless of water or some very weak solution, should never be made into the cavity of the uterus—there are other modes of topical medication far superior; and, secondly, that no strong application of any kind should be made to the endometrium, if there is any secretion in the uterine cavity, without previously washing away the secretion, and testing the tolerance of the organ, by these same mild injections. Dr. Nott has given the reasons. The simple repeated washing out of the cavity thus, as preliminary treatment, may sometimes effect a cure when you are not expecting it. To my remark concerning strong injections I would make an exception in the case of uterine hæmorrhage, when, after washing out the clots, it is sometimes necessary to inject solution of persulphate of iron in full strength.

This instrument, like the other two, is passed into the dilated cervical canal either upon a sound or by a pair of long dressing-forceps. If, for any reason, you wish to keep up the dilatation for a length of time, you have merely to apply a tampon, and the instrument will stay in place. I have thus kept it in position for a week. Suppose now that you have done with your detergent injections, and desire to make some more powerful application, you will then have recourse to speculum

No. 2, for the application of unguents or fluids to the endometrium by painting them over its surface. This has the same diameter as No. 1, but is somewhat shorter, penetrating only a quarter or half inch beyond the os internum; it has only two fenestræ, which are opposite each other, very broad, extending from an inch and a quarter above the vaginal extremity almost to the apex (which is a mere narrow strip between them), and placed right and left, so as to guide an applicator toward the cornua; the eye in the collar fixes its position. The best applicator is a springy steel wire roughened at the end and wrapped with cotton. Dipping this in your medicament, you pass it first to one side then to the other, and are perfectly sure both that you have touched every part of the endometrial surface, and that no superfluous drop can be left behind to breed trouble.

Moreover, if you fear the application has been too strong, you can easily mollify its effect by water or whatever bland wash you please. The womb cannot contract and retain the fluid, for any effort it may make to expel the speculum is easily overcome.

No. 3 is for strictly endotrachelial applications, whether by injection or by painting. This is about as long as the last, and has the same calibre; its upper end is closed; the fenestræ, three in number, and each one-fifth the circumference, begin at the vaginal collar and extend upward an inch and a quarter. While effectually guarding the metrial cavity against all invasion, this little speculum, by smoothing out the numerous and deep folds of the trachelial mucous membrane, enables you to command at once three-fifths of its surface in a manner that would be impossible by the armed probe alone; and by slightly rotating the instrument, you have the remaining two-fifths under command.

Incidentally I may add that these intra-uterine specula furnish a means of readily and completely separating the endometrial from the endotrachelial secretion, and obtaining either in a state of purity for chemical or microscopic examination.

Dr. Byrne said that he had lately presented a paper upon the subject to the American Medical Association, and would not anticipate its publication by any extended remarks. Most of the views put forth by Dr. Nott and Dr. Peaslee accorded with the results of his own observation. He had long since come to the conclusion that powerful caustics would best never be injected into the uterus. After long experience in their use he had entirely abandoned them. Latterly he had been in the habit of using milder liquid applications, especially solutions of sulphite of soda, sulphurous acid, tannin, etc. These mild liquids would easily flow out of the uterus if a proper catheter was employed. His own catheter was of peculiar construction, and being of size No. 6, required no preliminary dilatation of the cervix; for wherever intra-uterine medication was demanded there was no stricture of the internal os. The reflux channel was so arranged that, if it became at all obstructed by coagula, it could be cleared by a slight movement of the instrument. The speaker had become fully convinced that in all cases of very troublesome intra-uterine affection there was some constitutional dyscrasia; and that no topical treatment could be of any permanent avail without keeping this in mind and giving the most careful attention to constitutional treatment and hygienic measures.

Dr. Prince could heartily endorse the remarks of Dr. Peaslee. He had, for a number of years, practised dilatation of the cervix by means similar to Dr. Peaslee's, led to do so by one of those failures which are often more instructive than successes. Frequently employing the uterotome, he had been in the habit of keeping the canal open, after cutting, by sponge tents, till a case fatal from pyæmia induced him to discard them. Before this case he had seen others where serious disturbance followed the use of the tents, apparently from absorption of pus; and since then he had always employed a series of bougies to maintain the dilatation.

The speaker could not agree that it was safe to inject persulphate of iron for uterine hæmorrhage. In a case of miscarriage, in a lady of forty-four or forty-five years, where the bleeding was profuse and some astringent was necessary, he had injected five or six drops, at farthest, of Monsel's solution. The pain which followed was more violent than anything he had ever seen; and had he not carried a vial of chloroform in his pocket, he thought the woman would have succumbed to it. He was obliged to keep her under chloroform for an hour and a half. He had not since used the persulphate in such cases, but had found a plug of solid alum answer every purpose. He would never employ strong injections, but would introduce any powerful substance upon the armed stylet as recommended by Dr. Peaslee.

Dr. Chadsey had always opposed strong applications even to the neck or the mouth of the womb. He had many years ago given up the use of nitrate of silver; and he preferred anodyne applications, containing opium and calomel, made, not by injection, but with a brush or sponge, so that they would adhere to the parts. He narrated the case of a woman with cancer of the breast, who was seized with lancinating uterine pains. From the mouth of the womb, which was open wide enough to admit a full-sized silver catheter, there was discharged a dark, grumous fluid. Uterine cancer was diagnosticated. The Doctor injected through a catheter a solution of one part of pure carbolic acid in forty parts each of glycerine and water. Under this injection, with the administration of iodide of potassium and general tonics, the woman rapidly improved.

Dr. Messenger had found great success in arresting uterine hæmorrhage with the preparation lately introduced under the name of ergotine. So far as he had observed its effects, it produced no coagulation; but it arrested the bleeding with more promptness and less danger than any other agent he had employed. It had acted very happily in two cases which had, before its use, given him great trouble.

For making applications to any part of the uterus Dr. Messenger preferred, to the armed probe or wire, a syringe he had had made by Mr. Tiemann. It had a long flexible nozzle of pure silver, plated with gold, terminating in a bulbous extremity pierced with several small holes. The piston was graduated to minims. Wrapping a little cotton about the bulbous end, he introduced it to the exact point desired, and then expelled as much or as little fluid as he pleased. He thought he had thus succeeded in making applications not only to the uterus, but also to the neck of the bladder, more accurately than by any other means. With the cotton-wound wire, even if passed through Dr. Peaslee's speculum, you were apt to leave some part of the fluid, you knew not exactly where.

Dr. Garrish thought women ought to use the vaginal syringe as regularly as they washed their faces. No other application equalled the solution of tannin in glycerine.

Dr. Newmann insisted, with Dr. Nott and Dr. Peaslee, upon the absolute necessity of thoroughly cleansing the uterine cavities before making any remedial applications. Dr. Nott's catheter was admirable for the purpose. He himself employed for injecting the bladder a combination of this catheter with Dr. Byrne's, and he had also used it for uterine injection. He was accustomed to attach it by flexible tubing to the Croton water pipes, hot and cold, so as to regulate the temperature at will, and thus to wash out the cavities very freely. He objected strongly to the use of *cold* water, as he thought it often hardened the tissues much more than the nitrate of silver.

He could not agree with those who considered the nitrate such a dangerous remedy. True, it might do much harm if carelessly used; it could hardly fail to do so if the solid stick were thrust haphazard into the uterus. But if applied with judgment and precision to diseased tissues alone (especially granulations), and to these only long enough to stimulate and not to disorganize them, it was of the greatest value. He had for years used almost daily a solution of one part of nitrate of silver in three of water, and had not yet

found a single instance of harm to the patient. He applied it to the bladder through the endoscope.

Allusion had been made to the very destructive action of chromic acid. That was all true; the speaker had himself seen a mouse completely destroyed by it in a brief time, and even a hair pencil with its quill handle. Yet Dr. Emmet cured his patients with it. He touched none but diseased parts; the chromic acid became chromic oxide, and formed a scab beneath which the healing process went on. The dilated follicular cysts often found in the cervical canal, the speaker had never seen cured except by this means. In such cases, after dilating the canal with sea-tangle, he applied the chromic acid to the cysts, and often a single application was sufficient. Drs. Emmet and Perry even incised the uterus and then applied this acid within its cavity. But none of these powerful agents must be used at random, or kept too long in contact with the parts.

Dr. N. had often been asked whether the endoscope could be used for inspecting the cavity of the uterus. It could be readily introduced; but commonly the secretions of the part so obscured things that it was impossible to see the mucous membrane satisfactorily. It might probably be employed with success if the cavity could first be most thoroughly cleansed.

Dr. Peaslee would say one word regarding the use of the persulphate of iron in metrorrhagia, which he had before incidentally mentioned. He was prepared to defend his own use of it, had time allowed. Having employed the agent in perhaps one hundred cases, he had never seen any harm result, except that in one case it gave great pain. But he confined its use to a particular class of cases, in which there was great debility from loss of blood, and you could hardly excite any reaction of the uterus.

Dr. T. G. Thomas, the Chairman, was called upon, and remarked: I am the more willing to state my own views, because they are so entirely at variance with those I have heard expressed this evening. It requires some boldness, I admit, to take a stand in opposition to such an array of authority and experience as I see before me,—a boldness which I could hardly command, were it not that I have very strong convictions upon the subject. These I hope are not held without reason, as they certainly have not been lightly formed. The subject has always claimed my deepest interest, not only from its intrinsic importance and the fact that it enters so largely into my daily practice, but also because, as a teacher, I feel the weight of responsibility which rests upon me in guiding the practice of others.

Now, my impression is, that intra-uterine injections do not constitute an advance in the treatment of uterine diseases; that they have done and are going to do a good deal of harm; and that, though now they are popular, their evil results will cause them, after a more thorough trial, to be discarded.

In making such an assertion, I must, of course, sustain it by proof. I commenced the use of intra-uterine applications, both solid and fluid, at least ten years ago. At that time I was extremely fond of them, and treated many a case as endometritis of the body which I should now treat as cervical endometritis. One method which I very often employed was that brought forward by Dr. Lente, of dipping a probe into the fused nitrate of silver, and passing it up to the fundus uteri and around the cavity, so as to cauterize its whole surface. Once, after I had made such an application of the solid nitrate, the patient became dangerously ill with the symptoms of cholera morbus, due entirely to this cause. A year or two later, a lady, who had been for some time under my care for corporeal metritis and endometritis, became discouraged, and at my suggestion consulted one of the best gynæcologists of this city. I saw her again at the end of a week, when she had a phlegmon, the size of my fist, in one broad ligament. The inflammation had been set up by the introduction of an ointment of calomel through the canula of Dr. Lente.

I have mentioned these cases where solid applications to the cavity of the uterine body have done injury, merely to illustrate the fact that solid applications, which are less harmful than fluid ones, are, when made to this locality, not free from danger. Let us see how the matter stands with the injection of fluids. Dr. Nott has said that the entrance of any injected fluid into the peritonæal cavity cannot produce a serious effect immediately, but time must first elapse for inflammatory action to become established. In this statement I think that the Doctor is in error. A case which I saw some years ago in company with Dr. Peters, whom I see present to-night, bears upon this point. The lady was known to have a simple ovarian tumor, I think about as large as the fist. Called to her in the night, I found her almost in collapse, saying she was sure the tumor had broken. She was right, and her terrible prostration was due entirely to the entrance of the fluid of this benign ovarian cyst into the peritonæum. I recall the case of one of my students, who in lifting a trunk felt something give way, was at once violently collapsed, and finally died of peritonitis. The cause was in all probability a rupture of the vermiform appendix.

My own impression is that where intra-uterine injection is practised, a certain number of the cases will die from penetration of the fluid through the fallopian tubes. This certainly does produce the most intense agony, and the most sudden and fearful collapse. I remember that, while making such an injection, by means of a syringe with a screw-piston, each turn of which forced out a single drop of fluid,—when I had thrown but five drops into the uterine cavity, the patient exclaimed: "My God, doctor, you have killed me." Her sudden pain and terror seemed to me due to the passage of the fluid into the peritonæum—nothing else could have been quick enough. She went through a tedious course of pelvic peritonitis, barely escaping with her life.

But it will be said that in these cases the cervix was not dilated; had it been so, no evil would have resulted. I reply that the very dilatation so coolly talked of theoretically is itself attended by danger. Within a fortnight past I have had one of the most melancholy cases I have ever met in practice. The lady had come to me three months before with anteversion of the uterus. I had treated her with an anteversion pessary, and now considered that part of the treatment completed. So I told her, "I am to-day going to dilate the neck of your womb, and to do nothing else." I did this at my office, using three of Dr. Peaslee's dilators; and she left for her home at Staten Island, promising to write me. This was on Monday, of last week. Tuesday evening I was summoned to Staten Island, where I found this lady with violent pelvic peritonitis, of which she died on Sunday evening. I think the mischief was done by the dilatation of the neck of the uterus. Yet I am very sure that the dilators were passed with the requisite skill; for I spend much of my time in this practice, and this operation is one to which I have constant resort.

Some time since a gentleman wrote me, from St. Paul, Minnesota, that he had known a case where a small amount of a solution of iodine was injected into the cavity of the uterus, and the woman died suddenly of peritonitis.

Now, these are selected cases, I allow; and it is by no

means a final argument against any procedure that such selected cases should speak badly for it. The question is very different, however, from that in such a capital operation as amputation of the neck of the uterus, for example, which you enter upon expecting, and the patient and her f. ends expecting, that there is at least a chance of a fatal issue. Such an operation is justifiable, and often imperative, as offering the only chance for life, though it may be a very small one. But if the woman be suffering simply from some slightly annoying affection, she does not expect to die from the routine procedure you resort to for its relief; and you have no right to employ any means attended with such hazard.

Again, I see no necessity for intra-uterine injections. My impression is, that the uterus rarely contains over a drachm of fluid; and that it is an error to represent it as often containing a considerable amount of putrescent discharge. But if it have within it such fluid requiring removal, dilate the cervix, and replace the organ, if ante- or retro-verted, or flexed, and what is to hinder the fluid from coming out? The dilatation itself will accomplish much. Then, in addition, if necessary, give ergotine, or ergot, and general tonics; and if required, introduce the cotton-wrapped probe. Every one knows the difficulty of removing the plug of viscid mucus from the cervical canal. For this purpose I keep a supply of little bits of sponge, not larger than my finger's end. which, being wet and squeezed, will wipe the canal nicely, and then be thrown away. This done, I see no difficulty in passing up the probe armed with cotton, and painting over the whole internal surface.

For myself, I never use intra-uterine injections, even for the hæmorrhage of abortion. If we know anything about the pathology of uterine hæmorrhage, we know that it should be stopped by closure of the vessels by contraction of the tissue of the uterus itself. After delivery we all recognize that the only proper thing to do is to empty out the clots and stimulate the uterus to contraction. And even after abortion, I look upon the injection of styptics as a bad plan. Take, as an example, a case which came before me a few days ago. A woman had been bleeding for three months after an abortion. It seemed to me there must be something in the uterus to cause the flow; for, otherwise, what is there in an abortion to keep up hæmorrhage for such a length of time? In such a case, you may take it for granted that something has been left behind. The doctor in charge of the case consented to my dilating the cervix and introducing the curette. I took away a number of little bulbous bodies, remains of the placenta—those little granulations which bleed if you look at them, and pour out blood profusely if you touch them with a probe. The next day the hæmorrhage had completely stopped, and within a week the patient's general condition was greatly improved. I mention this not as a case important in itself, but as a type of many where success may be attained by a comparatively minor procedure—for I esteem the use of the curette as a far less grave operation than the injection of the uterine cavity.

I wish it to be distinctly understood that I have been objecting, not to intra-uterine medication by such means as those mentioned by Dr. Peaslee—the brush or probe, for instance—but to the special form of medication by injections; and I include even the injection of warm water, which I think can hardly ever be necessary.

If my remarks have seemed desultory, it is because I have left out a great part of what I wished to say, owing to the lateness of the hour. I have to thank the gentlemen for listening to them; for, indeed, it seemed almost a duty to express myself. My views are the result of careful thought, and I hold them with great strength of conviction. I feel that we shall soon see such unequivocally bad results from intra-uterine injection, that the profession will be forced to abandon it as a customary practice.

The Society adjourned.

STATED MEETING, JUNE 6, 1870.

DR. ELLSWORTH ELIOT in the Chair.

DR. W. B. NEFTEL read a paper upon *The Action of the Galvanic Current on the Sympathetic Nerve.* It was long and elaborate, containing much of theoretical interest and practical value; but it was so crowded with detail that an abstract would do it no justice.

DR. GRISCOM presented a resolution, which was carried, tendering the appreciation and thanks of the profession in New York, as represented by the Society, to Baron Von Diergardt, of Bonn, Germany, for his liberal donation to the German Hospital of this city.

The Society adjourned. Its next meeting will be held on the first Monday in September.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, APRIL 1, 1870.

DR. ISAAC E. TAYLOR, PRESIDENT, in the Chair.

TUBERCULOSIS IN INFANCY AND CHILDHOOD.

DR. J. LEWIS SMITH read a paper on *The Causes and Anatomical Characters of Tuberculosis in Infancy and Childhood*, which we presented in the RECORD of June 15th.*

DR. JACOBI.—This is just such a paper as I expected to hear—a concise and positive review of all that has been done in the investigation of tuberculosis, giving us in condensed form nearly everything that is known upon the subject. It affords, therefore, little room for discussion; but upon a few points I may say a word. Perhaps what I have to say may be contained in those parts of the paper omitted in the reading.

We do not find tubercles except in the walls of small vessels. Only a short time ago it was the opinion that they would be found in the walls of small blood-vessels or capillaries; but lately it appears to be the prevailing view that the lymph-vessels are the only ones where tubercle may be found. Thus it may be explained that the principal constituent of new-formed tubercle is always of a lymphoid character. The description given by the Doctor coincides exactly with that of lymphoid cells.

I was struck by the remark concerning a connection between pulmonary tuberculosis and the condition of the bronchial glands. The Doctor states that, next to the lungs, the bronchial glands are oftener affected with tubercle than any other organs. I believe the relation of these glands to tuberculosis in the lungs, or rather to general tuberculosis, is more like that described in the last words of his paper—that tuberculosis in the lung is the result of absorption, not of tubercular matter but of old disintegrated matter. It is not necessary that the matter absorbed should be tubercular; if it is simply granular, any disintegrated material will be likely to bring about tuberculosis in a predisposed person. So far as inflammation

* An accident has delayed till the present number the publication of this report, which was prepared to accompany Dr. Smith's Lecture.

of the bronchial glands is concerned, we find it in almost every infant that fails of proper nutriment or assimilation. There is no infant of this description, of six or seven months, without enlargement, hyperplasia, of these glands. In rachitic cases, by the time they are ready to die, we find enlargement of the bronchial glands, which has developed the peculiar bronchial catarrh so difficult to treat.

To the compression of the pneumogastric or of the recurrent laryngeal nerve by the enlarged glands I attach less importance than does the Doctor. Were it so important, we should certainly find more nervous symptoms. Where we have to deal with a neurosis of the pneumogastric, we have an almost incessant, very characteristic, hoarse or barking cough, such as I see perhaps once in two, three, or four years; and sometimes without any complicating affection. This we should have if the bronchial glands were pressing upon the nerve.

I cannot agree that the enlargement of the mesenteric glands, so common in infants, is chiefly tuberculous. The statistics of Rilliet and Barthez are of no value here; for when they were compiled the difference was not known between tubercular and caseous degeneration. We have no right to speak of tubercular degeneration unless we find, in those portions of the glands not yet disintegrated, the lymphoid, tubercular bodies. In the mesenteric glands, for the most part, we do not find these, but simply a fatty detritus. We know that we seldom meet a case of chronic diarrhœa in infants without enlargement of the mesenteric glands. This is the result, in the first place, simply of over-nutrition of the whole region. Catarrh of the intestine means hyperæmia; and this, if not relieved, will produce chronic inflammation and resulting disintegration. Either there is enlargement of the proper glandular elements, or there is hypertrophy of the connective tissue. In the first case we soon have caseous degeneration; in the second, we have induration, shrinking, and atrophy of the glands. Imagine now that a case of the first description lasts a number of months. Degeneration takes place, caseous softening, the formation of an abscess. If the lymphatic vessels entering such glands are not stopped up, the result will be that the matter will be absorbed and spread all over the system. Why should this produce constitutional tubercle? I believe the cause is, that every foreign substance entering the blood will light up a fever. And any disintegrated material entering the system need not go far before finding its way into the veins or lymphatics. The fact that in the infant we see tuberculosis invading almost all the organs at one and the same time I think can be best explained in this manner. It is favored by the great delicacy of the walls of the minute capillary vessels, which are, if at all anything else, little more than a layer of epithelial cells.

The Doctor has stated correctly, as I believe, that tubercle is very rarely found upon the mucous membrane of the intestine. I believe that tuberculosis upon the interior of the intestine is always due to material that has been swallowed. I have lately presented to the Pathological Society a specimen of typhoid intestine, where the lesions (ulcerations) were found not only in the usual place, but quite low down in the colon. The case had lasted a very long time, and in all probability these ulcerations of the lower bowel were due to morbid material washed down there. Similarly I conceive that tuberculous ulcerations of the inner part of the intestine are due to morbific matter swallowed. The tubercles ulcerated in the lung are coughed up, but not expectorated. The matter is swallowed and poisons the intestine—not the stomach, where it has little time to rest, and where tubercle is very rare. The presence of tubercle in the larynx is probably the result of contact also.

Where we find transparent tubercle, it shows that the tubercular process is not old. The oldest tubercle in the specimen shown here to-night cannot be many days older than the transparent ones. It requires but very few days for transparent tubercle to assume the yellowish appearance, this being the result of accumulation and compression of the new-formed cells.

As to fatty degeneration of the liver, I think we see almost as much of it in infants and children as in adults. It is not necessary that there should be anything beyond faulty nutrition to produce it. Every tissue not fully formed, especially a cell-tissue, has a tendency to fatty degeneration. The liver, being pre-eminently cellular, is particularly liable to this degeneration when there is malassimilation.

Dr. J. Lewis Smith.—I have now made a large number of post-mortems of infants dying from what is called "inanition," and I believe that in most of these cases we shall find hyperplasia of the mesenteric glands—not so much of the bronchial—but as a rule shall not find caseous degeneration. When this last has occurred, we commonly find also tubercles in the lungs.

As to cerebral symptoms from the enlargement of the bronchial glands, I agree with Dr. Jacobi that it is only a small number of cases in which such symptoms arise, due to passive congestion of the brain from pressure upon the venous trunks, or to pressure upon the pneumogastric.

Dr. Jacobi.—Might I venture upon an explanation of the fact which the Doctor has just stated—that we find less caseous degeneration in the mesenteric glands than in the bronchial. Perhaps the physiological cause may be this: Every change of this kind is connected with hyperæmia. The mesenteric glands will be affected by intestinal congestion in their neighborhood; this congestion, however, spreads over a large surface, and may not be so active as in the bronchial glands. In the immediate vicinity of these latter is a fœtal organ, the thymus gland, which after birth rapidly diminishes in size; and I can imagine that its diminution may tend to cause collateral hyperæmia in its immediate vicinity, and thus produce a rapid and considerable swelling of the bronchial glands. So in children with rachitic symptoms we see bronchial degeneration at only a few months of age. I do not know that this is the true reason why the bronchial glands should exhibit such a great tendency to excessive swelling and rapid cell-degeneration, but it strikes me as possible.

The meeting adjourned.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

SEVENTH ANNUAL MEETING.—FIRST DAY.

The Society met at the Masonic Hall, Newport, R. I., on Thursday, July 21, 1870. The meeting was called to order at 11 A.M., by the President, H. W. Williams, M.D., and the minutes of the last meeting were read by the Secretary, H. D. Noyes, M.D. The following-named members were present:

Dr. H. W. Williams, B. Joy Jeffries, G. Hay, Boston.
C. A. Robertson, Albany.
C. R. Agnew, C. M. Allin, Francis Delafield, H. Knapp, E. G. Loring, H. D. Noyes, D. B. St. John Roosa, New York.
John Green, St. Louis.

The President named the Committees as follows:
On Order of Business—Roosa, Jeffries, Robertson.

On New Members—Agnew, Green, Delafield, Loring. Dr. Jeffries read the report on the progress of ophthalmology. This exhaustive report received a vote of thanks from the Society.

Dr. Allin read a case of cyst of the iris, cured by operation, with a microscopical description by Dr. Althof.

Dr. Knapp made some remarks upon his case of cyst of the iris, published in the Archivs für Ophthalmologie, which he was requested to reduce to writing.

Dr. Allin read a case of double detachment of the retina, supposed to be *glioma*.

Dr. Jeffries read a report of a case of *glio-sarcoma* of the retina.

Dr. Knapp related a case of glioma of the retina.

Dr. Delafield read an exhaustive paper, illustrated by five cases, on tumors of the retina.

Dr. Allin read a paper on a case of diphtheritic conjunctivitis, in which canthoplasty was performed.

A general discussion on so-called canthoplasty, that is, elongation of the palpebral fissure, followed, in which Drs. Noyes, Agnew, Roosa, Knapp, and Allin, participated.

Dr. Noyes demonstrated an operation intended to increase the effect of the division of the orbicularis. Dr. Roosa spoke of the possible dangers of the great amount of dissection in such an operation, and advanced a case in point.

Dr. Knapp thought the name canthoplasty should not be given to the mere elongation of the fissure, which was done years ago by Graefe and others in gonorrhœal and phlyctenular conjunctivitis.

The following names were reported by the Committee on New Members, and the gentlemen were elected members of the Society:

Drs. Pooley, Eno, and Aub, New York; Drs. Norris and Thompson, of Philadelphia; Dr. Willard, of Boston; Dr. Miller, of Providence. Drs. Norris, Pooley, Thompson, and Miller, took their seats as members.

The following named gentlemen were present by invitation:—Dr. Green, Boston; Dr. G. A. Peters, Dr. T. F. Cock, and Dr. Hodge, New York.

Adjourned till 7½ P. M.

Evening Session.

The Society met at 8 P.M.

The name of Dr. S. L. Jones, of Chicago, was reported by the Committee, and Dr. Jones was elected a member, and took his seat with the Society:

Dr. Allin made some remarks for Dr. Althof on the treatment of asthenopia, causing phlyctenular conjunctivitis by prismatic glasses.

Dr. Roosa read a case of conjunctivitis and keratitis, having some peculiarities.

Dr. Noyes read a case of foreign body in the vitreous, illustrated by a drawing by Dr. Eno. The exact position of the body in the vitreous was primarily diagnosticated by Dr. Noyes.

Dr. Pooley read a case of foreign body in the eye, the position of which was diagnosticated by the interruption in the field of vision, as first done by R. Berlin.

Dr. John Green read a paper on the Treatment of Strabismus Convergens through the accommodation.

Dr. Agnew read a report and exhibited photographs of a case of advancement of the internal rectus, to relieve a deformity caused by an ancient operation for convergent squint.

Dr. Loring demonstrated, by means of a glass-tube filled with fluid, placed in front of a reflecting surface, and also in front of a plane mirror, that Jaeger's explanation of the double contour seen in the retinal arteries was incorrect; and that it was really due to the reflection from the tissue behind the artery, the light passing through the anterior and posterior walls of the vessels.

This beautiful experiment was considered conclusive, and after some discussion by Drs. Knapp and Loring, it was understood that the *refraction* which the light underwent in the blood column, as well as reflection, which caused the phenomenon.

Dr. Jeffries read three cases of herpes zoster ophthalmicus.

Adjourned.

SECOND DAY.

The Society met, and was called to order at 10 A.M.

Dr. Jeffries reported thirteen cases of Passavant's operation for the removal of posterior synechiæ, illustrated by figures.

Dr. Thompson read a paper on an additional test for the degree of ametropia. This test consists essentially in placing before the eye a perforated screen, and regarding a light point, say 20 feet distant; when in hypermetropia or myopia two points of light are seen, while in emmetropia but one is seen. It is Scheiner's test for the accommodation adapted to the present knowledge of errors of refraction. Dr. Knapp thought the test insufficient, because the accommodation could not be relaxed in any test, and because Lesting's diagrammatic eye was used, while in point of fact each individual eye differed in the optical axis. Dr. Thompson's practical demonstrations of his method were, however, very satisfactory.

Dr. Knapp exhibited ophthalmoscopic drawings of cases of retinitis pigmentosa, morbus Brightii, and choroidal perivasculitis.

Dr. Hay exhibited an apparatus to illustrate the apparent form of the inverted image in astigmatism.

Dr. Knapp made some remarks on neuro-retinitis in cases where the vision was I. Dr. Loring related a case, and some discussion ensued as to the cause and seat of lesion.

Dr. Agnew reported a case of blepharoplasty, where a series of operations was done to relieve a coloboma of the lower lid.

Dr. Noyes related the history and exhibited photographs of a case of ectropion from exophthalmia, in which he enucleated the eye, and closed the palpebral fissure to relieve a very distressing deformity.

Dr. Agnew read a paper by Dr. J. S. Prout, On the use of Quinine upon the Conjunctiva.

A paper by Dr. Robertson was read, by title, "On some Peculiar Reflex Symptoms in a Case of Traumatic Lesion of the Eye."

Dr. Knapp then gave some practical points in the performance of the peripheric linear operation for cataract, and started a discussion on the shape of incision, laceration of the capsule, the bandage, which was participated in by Drs. Agnew, Noyes, and Jeffries.

The Society resolved to meet at Newport, R. I., on Thursday, July 22, 1870, at 9 A.M.

The following officers were re-elected.

President—H. W. Williams.
Vice-President—C. R. Agnew.
Recording Secretary—H. D. Noyes.
Corresponding Secretary—H. Althof.
Committee on Progress of Ophthalmology—B. Joy Jeffries.
Publication Committee—E. G. Loring, Jr., D. B. St. J. Roosa.

The Society then adjourned.

AMERICAN OTOLOGICAL SOCIETY.

THIRD ANNUAL MEETING.

The Society met at the Ocean House, Newport, R.I., on Wednesday, July 20th, at 10½ A.M. The Society was called to order by the President, Dr. H. D. Noyes, of N. Y. In the absence of the Secretary, Dr. Rider, Dr. R. F. Weir, of N. Y., was elected Secretary *pro tem.* The following members were present:—

Dr. J. Orne Green, Dr. C. J. Blake, Dr. W. W. Moreland, Boston.

Dr. C. R. Agnew, Dr. H. D. Noyes, Dr. H. Knapp, Dr. D. B. St. John Roosa, Dr. R. F. Weir, New York.

Dr. C. E. Robertson, Albany.

Dr. John Green, St. Louis.

The minutes of the last meeting were read and approved.

The President appointed Drs. Agnew, Roosa, and Green (Boston), an Executive Committee, to nominate officers, committees, and arrange an order of business.

The Committee reported the following named as Committee on Nomination of New Members:—Drs. Noyes, Green, Blake, Weir, Roosa.

The committee reported the names of the following gentlemen, who were elected members of the Society:—

Dr. T. R. Pooley, Dr. C. I. Pardee, Dr. J. H. Hinton, New York.

Dr. H. N. Spencer, St. Louis.

Dr. H. Pinkney, Dr. A. Buck, New York.

The report of the Treasurer was read and referred to an Auditing Committee, Dr. Blake.

The report on the Progress of Otology was read by Dr. J. Orne Green. A vote of thanks was given Dr. Green for his exhaustive report.

Dr. Moreland, of Boston, read a paper on Occlusion of Meatus Externus by Cutaneous Layer.

Dr. R. F. Weir read a case of hair ingrowing upon the membrana tympani.

Dr. C. A. Robertson gave the history, and exhibited a case, of anal polypus with facial paralysis.

Serious hemorrhage had occurred on attempts to remove the growth.

He asked the views of the Society as to the proper procedure. Dr. Roosa advised the use of an anæsthetic, and the thorough removal of the growth, plugging the meatus in case of hemorrhage.

Dr. Agnew suggested that a microscopic examination be made, and then the removal attempted.

Dr. Knapp thought well of galvanic caustic for the removal of large polypi.

Dr. Roosa read a paper on the Mastoid Process in inflammations of the middle ear. The paper contained cases and a historical account of the operation of perforation of the process.

Dr. Agnew related a case of trephining the mastoid process.

The subject of these papers was discussed by Drs. Knapp, Orne Green, and Weir.

Dr. H. D. Noyes read a case of the use of the bougie in the Eustachian tube, and Politzer's eyelet in the membrana tympani.

Dr. Weir, in the discussion that followed, exhibited some bougies, and discussed his method of using the instrument.

On motion Dr. Weir was requested to put his remarks in writing, and submit them to the Publishing Committee.

Drs. Orne Green, Agnew, Knapp, and Blake discussed Dr. Noyes' paper.

Dr. J. Orne Green read a case of Epithelioma of the Auricle.

Drs. G. A. Peters and F. Delafield, of New York; Norris and Thompson, of Philadelphia, were present by invitation.

Adjourned at 2½ till 7 P. M.

EVENING SESSION.

The Society met at 7½ P. M. The Committee on New Members reported the name of Dr. Arthur Mathewson, who was elected a member of the Society.

Dr. T. F. Cock, of New York, was present by invitation.

Dr. Moreland read a paper on Foreign Bodies in the External Auditory Canal. Remarks were made by Dr. Roosa, Noyes, and others.

Dr. A. H. Buck read a paper on Angioma of the Tympanum, illustrated by a microscopic specimen and drawings.

Dr. John Green reported a case of Aspergillus.

Dr. Noyes made some remarks on the catheterization of the Eustachian tube through the opposite nostril, and exhibited some instruments with a double curve, which he had devised to facilitate this manœuvre.

Dr. Noyes also exhibited a binocular ophthalmoscope adapted for the examination of the membrana tympani.

Dr. Weir read the full report of a case already quoted in Roosa's translation of Tröltsch on the Ear, of ununited fracture of the handle of the malleus.

Dr. Roosa read two cases of hemiplegia occurring in coincidence with aural disease.

Dr. Knapp reported a case of congenital closure of the meatus.

Dr. J. Orne Green read a case of epithelicma of auricle.

A paper on the use of steam in sclerosis of the middle ear was read for Dr. Pardee, the author.

Dr. John Green read a paper detailing some experiments which he had made in a submarine chamber.

All these papers were referred to the Publishing Committee. On recommendation of the Executive Committee, the following-named officers were elected for the ensuing year: President, H. D. Noyes, M.D.; Vice-President, E. L. Holmes, M.D.; Secretary, J. Orne Green, M.D.

Committee on Progress of Otology: A. H. Buck.

Publication Committee: C. E. Hackley, M.D., R. F. Weir, M.D.

The Society then adjourned, subject to the call of the Secretary; it being understood that it be one day prior to the prospective meeting of the American Ophthalmological Society.

Gastro-Elytrotomy First Proposed.—Prof. T. Gaillard Thomas, M.D. (*Am. Jour. of Obstetrics*), recently read a paper before the Yonkers Medical Association on "Gastro-Elytrotomy," and remarked as follows: To avoid section of the peritonæum and uterus (Cæsarean section), in 1820 Ritgen of Germany proposed an operation which he styled gastro-elytrotomy. So far as his researches have enabled him to discover, this operation has attracted the attention of but four obstetricians: Jörg in 1806, Ritgen in 1820, Physick in 1822, and A. Baudelocque in 1823.

The Admixture of Sexes in Medical Classes, Hospitals, and Dissecting-Rooms.—Two of the most distinguished Professors of the University of Edinburgh—Professors Christison and Laycock—object to the admixture of the sexes in the study of medicine in medical institutions. The University has voted "No" to the proposition of mixing the sexes in medical teaching.

Correspondence.

THE HYPODERMIC USE OF QUININE.

To the Editor of the Medical Record.

Sir—In your journal of June 1st, 1870, p. 167, you publish an abstract of the history of a case, from the *New Orleans Journal of Medicine*, by Dr. E. P. Sale, of "Death from Tetanus produced by the Administration of Quinine Hypodermically." You were also pleased, in your recent notice of my paper on the uses and abuses of quinia and its salts, published in the Transactions of the American Medical Association for 1869, to call the attention of the profession to the fact that I therein class the hypodermic use of quinine among the abuses of the drug, and you did so with your approbation.

These circumstances, and more especially this late history of a fatal result from the hypodermic use of the medicine, have appeared to me sufficient reason for an effort to give what I do say in that paper, on this abuse of quinine, a more general circulation among the profession; and to that end I have made the following abstract of the substance, and much of the letter, of the portion of said paper which treats of the subcutaneous use of quinia and its salts, and send it to you with the hope that the Record may carry it where it will be the means of saving human life, and of preventing a vast amount of unnecessary suffering. In that paper, at p. 227 of the Transactions for 1869, I say: "The introduction of the substance into the areolar tissue of various parts of the body, or into the veins, I regard as the greatest abuse of all the abuses of administration of quinine. This is an innovation of therapeutics of modern origin. It followed very slowly upon this manner of using the neutral salts of morphia and other similar substances, and has been very cautiously adopted by the profession."

The reasons for this caution are obvious, and are alluded to by all the advocates of this manner of administering quinine, viz., its insolubility except in decidedly acid fluids; nor have I yet seen any satisfactory argument or published experience which, in my judgment, outweighs the objection this fact affords to the subcutaneous employment of quinine.

The objections to this method of introducing the salts of quinia into the system may be arranged in the following order: First, it is a painful operation, both as to the introduction of the instrument, as well as following the permeation of the tissues by the fluid injected. So considerable is this latter pain, that morphine has been suggested and employed in combination with the quinine to prevent or alleviate it; and Dr. Bartholow, one of the advocates of this method of medication with quinine, suggests the local anæsthetic use of ether spray to prevent the pain attending the puncturing of the skin with the injecting needle. (Transactions of the Connecticut Medical Society for 1868, p. 1.5.)

Second, the operation is followed by inflammation in the part permeated by the fluid, an inflammation which creates more or less irritative fever, and not unfrequently results in suppuration at the locality; or, as we now see, may induce fatal tetanic disease.

Third, the possible danger of injecting a vein with not alone an acid fluid, but with bubbles of air.

Fourth, it is rarely, if indeed it is ever, a necessary or even expedient operation.

It is claimed by some that the acid added to effect the solution is rather a source of safety than of danger, the real danger arising from the presence of undissolved particles of the salt, or of dust or other extraneous matter that may by accident be found in the solution. Others, however, recognizing the liability of the most carefully prepared acid solutions to excite troublesome inflammatory action in the part, have proposed the etherial solution of quinia for this purpose as one less likely to produce accidents.

One grain to six minims of ether is recommended as a solution of proper concentration. (Bartholow, op. cit., pp. 105, 106.)

If we are allowed to judge of the merits of this proposal by the light of the experience of Dr. Sale, we cannot but regard it as even more dangerous than the use of the acid solution; for he adds to his report of the case of fatal tetanus caused by the subcutaneous use of an etherial solution of six grains the remark that "this is the fourth case out of ten in which he has had cause to regret resorting to this method of medication, on account of the violent inflammation which has been the consequence."

The literature upon this whole subject, therefore, goes to show that, under the most favorable circumstances, and by means of careful filtration, and in very small quantities, the subcutaneous use of quinine is attended with much danger, either in acid or etherial solution; and if, by a very possible accident, the etherial solution should reach the cavity of a vein, I should be prepared to hear that its conversion into vapor by the warmth of the blood had caused sudden fatal results.

How dangerous, then, must it be as a system of medication for camp and field hospitals! But that the readers of the Record may form their own conclusions, I add the following abstracts. The results of the experiments of the Committee of the Medical and Chirurgical Society are most instructive in this connection. They "found that neutral solutions as a rule were tolerated, but that very acid and very alkaline solutions were apt to cause irritation." They also "found that a drug injected subcutaneously was far less rapidly absorbed and less intense in its effects than when introduced into a vein." (Medico-Chirurgical Transactions, vol. xxxii., p. 561, 1867.) As an index of the degree of irritation produced by the injection of a solution of quinine into the subcutaneous areolar tissue, I regard the following statement of the committee as important. They found that "when the drug was injected into the cellular tissue, considerable elevation of the temperature was observed, this symptom being slight or inappreciable when the drug was taken in the same quantity by the mouth or by the rectum." Yet, in the face of these facts, a prominent advocate for this use of the medicine states that "it is a remarkable fact that the cure of malarious disease by the subcutaneous injection may be accomplished without any disturbance of the vascular system, without any alteration of the normal thermal line, and without any disorder of the cerebral functions." (Bartholow, op. cit., p. 105.) These and many similar ones which the literature of this subject furnishes, are most seductive and dangerous declarations, as no doubt Dr. Sale and many other misguided physicians are now able to attest.

While the Medical and Chirurgical Committee conclude that this manner of using various soluble substances is often advantageous, as securing greater intensity and rapidity of action, and include quinine among them, they add that "some caution is requisite in giving large doses of this drug, as irritation may arise from its presence under the skin. And further, "that, as a general rule, only clear neutral solutions of drugs should be injected; for such solutions rarely produce local irritation;" and they finally conclude that

"this plan of medication is most likely to be adopted where very rapid and decided effects are required from drugs which are operative in small doses." (Op. cit., p. 589.) During the discussion which followed the presentation of this report of the committee, Mr. Moore, who is quoted by some of the advocates of this method of using quinine as authority, remarked that large doses of the medicine introduced in this manner "always gave rise to suppuration; that even fifteen minims, in one case, produced this, and that five or six minims was the best quantity." These statements I regard as explanatory of the meaning of the terms *large* and *small* doses, as used by the committee, that they do not mean therapeutical, but simply physical quantity.

It would seem, however, that the physicians of the New York Hospital have had better results than Mr. Moore. According to their report, they are in the practice of giving thirty-five to seventy minim injections of quinine, with comparatively rare occurrence of suppuration at the point of introduction, notwithstanding their usual dose thus given contains more than one-fifth of a minim of strong sulphuric acid, and is consequently in a strongly acid solution. They had, however, been obliged to treat six abscesses, at the date of the report, resulting from the local inflammation produced by the injection, and they remark that when this kind of trouble was about to ensue, the *swelling normally consequent upon the injection* increased after the second day, and redness, together with beating pain, was noted. And besides these abscesses, they, with all the nice care to filter and prepare the solution, not unfrequently met with what they term phlegmonoid swelling at the seat of the injection.

Among the French physicians, the most recent contributor to this subject is Jules Arnould, who, after relating an extensive experience of a successful character in Algeria, remarks that the disadvantage of this method is the action of the substance upon the subcutaneous cellular tissue. He thinks, however, that a very careful preparation of the solution might reduce this liability to disagreeable effect to an insignificant minimum. Arnould's prescription was quinine in twelve parts of water, and the addition of a *few drops* of sulphuric acid, a totally indefinite quantity, but no doubt resulting in the production of a decidedly acid solution, though he remarks that the nearer neutral it is the less danger there is from its use. While he thinks that it will require only about two-thirds as much to produce the same effect as when given by the mouth, he does not think that this use of it should supersede its administration by the mouth, wherever it can be done without inconvenience to the patient. Though Dr. Bartholow has been so unfortunate as to produce large abscesses by this subcutaneous injection of quinine solutions, he, by dint of the most exact and delicate care in the preparation, as well as in all the steps of the administration of the solution, thinks he has attained such results as to justify him in accepting and recommending it as an established practice. Dr. Sale's experience demonstrates how much practical reliance can be placed upon such conclusions and recommendations. With all this evidence of the danger attending the subcutaneous use of quinine before us, we must have very weighty counterbalancing advantages to justify its continuance, or there must be the excuse of some insuperable difficulty in the way of its administration by the mouth or by the rectum.

The advantages claimed are, promptness of action, and greater efficiency, and more permanent effect.

With regard to the first claim I would say that, while the evidence decidedly sustains it, as respects the administration of the drug by the stomach, it fails to sustain it practically as respects the rectum, so that this alleged advantage of the promptness of the action of quinine, used hypodermically, will rarely if ever hold good as respects its use in perfect solution by the rectum. The Medical and Chirurgical Committee found that absorption of quinine from the subcutaneous areolar tissue, as well as from other parts, was liable to great variations as to rapidity. In one experiment 3 grains were absorbed from the areolar tissue in 35 minutes; in another 3 grains were absorbed in 4 minutes; in another 5 grains were taken up in 8 minutes. At the same time it was found that in one experiment 3 grains were absorbed from the rectum in 35 minutes, the precise time occupied by the areolar tissue. In another it took 45 minutes, and in a third experiment 5 grains were absorbed in 10 minutes. Upon these results the Committee issue the following, to me, unaccountable conclusions, viz.: "Not only, then, is rapidity of action and completeness of result advantages belonging to this method of exhibiting quinine, but also economy of material—a considerable recommendation to medical men on foreign stations, and to travellers in countries where intermittents prevail and the remedy is scarce."

I submit that they have furnished scarcely sufficient data to warrant so positive and forcible a deduction.

As to its efficiency and economy there are very diverse opinions. Arnould thinks that about two-thirds the amount of the medicine is required, when administered in this way, that is needed by the mouth—an opinion concurred in by Dr. Bartholow. Mr. Moore, in his early reports on the subject, thought five-sixths might be saved in this method of administration.

The New York Hospital physicians, however, found that, in the class of cases which came under their charge, this estimated economy "was far too high." "Four grains of the medicine," they say, "were needed to break an attack of tertian fever, and that fully eight were required for a quotidian." This, however, does not comprise all the medicine used in the treatment of the cases, as is clearly shown by the history of three cases which immediately follows. The first case, for example, consumed 16 grains; the second, 44 grains; and the third, 42 grains. The reporter adds the statement that the management of these three cases gives a correct idea of the general management of the "common intermittent" at that hospital by the subcutaneous treatment. This makes an average of about 35 grains used in the treatment of "common intermittents;" from three to four times the amount stated as sufficient by Dr. Bartholow. (Op. cit.)

If we now turn to this same reporter's statement of the old treatment at the New York Hospital, we find that for simple tertian intermittents, if kept under treatment a week, they consumed 56 grains, against 44 grains by the new method. Taking this as a statement of absolutely necessary amounts of quinine for the treatment of intermittent fever, when used by the mouth, it appears to me a very trifling economy, to be placed against the great and manifest objections and dangers of the subcutaneous method. But in the treatment of the common intermittents by the old style, at this hospital, an entirely unnecessary amount of quinine was employed.

Thirty grains is a full quantity for the treatment of a common tertian or quotidian intermittent; indeed it may generally be arrested with fifteen or twenty. I have arrested thousands of cases of quotidian intermittents with ten or fifteen grains of the sulphate of quinine.

Four grains, the same as employed by the New York Hospital physicians subcutaneously, was a very common dose, and a successful one in my tropical practice, as an antiperiodic, given by the mouth, and I am convinced that if that amount were given by the rectum, in perfect solution, it would be as effective as under the skin.

Stillé credits Trousseau with the statement that the dose of quinine in solution by the rectum is rather smaller than by the mouth. He also quotes Kuhn as authority for the statement that the dose of quinine by the rectum, if much diluted, is about half that required by the stomach.

The Medical and Chirurgical Committee found that the difference between the effect of quinine given by the mouth and by the subcutaneous areolar tissue is "more marked than between the rectum and areolar tissue." (Op. cit., p. 574.) On the other hand, Dr. Bartholow says, "We have ascertained that four times the quantity is required by the rectum that is necessary by the stomach, to produce a given effect." (Op. cit.) He is, however, in conflict with the most competent authority, and with my own positive knowledge, in this matter, a fact which would be difficult to explain but for his remark that by "suppository, or by clyster," he has found the rectum the best channel through which to introduce quinine in certain cases. (Op. cit., p. 121.) It would appear that he has ignored the fact that the *rectum is not a digestive organ;* and that, consequently, substances introduced into it, requiring digestion and solution, are more or less slowly and partially appropriated. To this class of substances belong quinine suppositories and quinine clysters, made with either pure water or some emulsive fluid. Had he, on the contrary, introduced the quinine in solution with water, he would have found that the rectum, as an absorbing organ, has hardly an equal in the body, and that his results would have agreed with those of other experimenters. My own oft-repeated observations upon the action of quinine, when given by the mouth and by the rectum, have convinced me that the dose for any purpose, if in solution, is never more, and as a rule very decidedly less, by the rectum than by the mouth.

Now, as we have already seen that the rapidity of the action of the drug, when administered in this manner, is practically about the same as when introduced into the areolar tissue, it becomes obvious that, so far as any practical result goes, the claims of promptness of action and economy of material for the subcutaneous use of quinine, as compared with its use in solution by the rectum, must be abandoned as not at all sufficient to justify the danger attending this method of administration.

As to the claimed permanency of the action of quinine introduced into the areolar tissue, I cannot but suspect that there has been some error in the observations which led to such a conclusion. The very fact that the medicine is promptly absorbed, leads me to infer that it is equally promptly eliminated, and consequently that its effect must be less permanent. I therefore see no physiological reason for the statement that quinine exercises a more permanent effect when introduced under the skin than when taken in any other way. The evidence that quinine introduced into the areolar tissue exercises a more permanent effect than when taken by other channels, is, so far as I have seen, furnished by the pulse and temperature of the body, signs which are fairly accounted for by the irritative fever produced by the local irritation of the injection.

Individually, I have fortunately no experience with the subcutaneous or intravenous use of quinine. Ever since I have thought of it at all, I have regarded it as a dangerous and unnecessary method of using the medicine; and the occasions in which the sulphate in pill, or other form, is objectionable by the mouth, and impracticable in solution by the rectum, I have never yet met with, and I presume will be very rarely seen. In all cases where a prompt action of the medicine is desired, as well as in cases where objections to its administration by the mouth exist, or in cases where economy of the drug is important, it should be given by the rectum in perfect solution, of a strength of not greater than ten grains to the ounce of water. The rectum tolerates such a solution with little or no inconvenience, and absorbs it very rapidly; and so long as this is the case, I insist, and I am sustained by the accumulating recorded experience upon the subject, that the use of the areolar tissue, or a vein, for the introduction of quinine into the system, is not only an unnecessary but a dangerous abuse of administration.

Respectfully yours,

STEPHEN ROGERS.

249 WEST 42D STREET, June 13, 1870.

Medical Items and News.

BOSTON MEDICAL AND SURGICAL JOURNAL.—The editorial management of this journal has passed into the hands of Dr. Francis H. Brown. Dr. Luther Parks having retired.

RECORD OF MORTALITY IN BERLIN.—In the months of January and February, 1870, there were 2,963 male births, and 2,807 female births: total 5,770, of which 500 boys and 446 girls were illegitimate. Fifty-one times there were twins and twice triplets.

One thousand and seven couple were married. Deaths 3,755—1,967 males, and 1,788 females. Under one year, 1,331; above 15 years, 1,689.

DEATH OF A NOTED ENGLISH SURGEON.—Mr. Nunnely, of Leeds, the accomplished surgeon and medical jurist, died on the 1st of June, aged 62.

DEATHS FROM CONSUMPTION IN THE UNITED STATES.—The average number of deaths from consumption, according to the census of 1860, was one in 1,447, while in the State of Florida it was one in 254. The most favorable time for phthisical and nervous patients to reside in Florida is from early in November to the first of May. The mean temperature during 20 years at St. Augustine, ranged from 57.03° in January to 80. 90° in July.

MANGANESE IN BLOOD AND MILK.—Professor Polucci, of Italy, has discovered the constant presence of manganese in the human blood. Manganese was also found in 34 analyses of milk, 23 of which were human, 4 from the cow, and 4 from the goat.

A NEW HOSPITAL IN LIVERPOOL, ENGLAND.—On the afternoon of June 7th, Lord Derby laid the cornerstone of the new Stanley Hospital, Liverpool.

A NOVEL USE FOR CROTON WATER.—Prof. Chandler, chemist to the New York Board of Health, in his interesting report on the milk supply of New York, estimates that for every three quarts of milk there is added one quart of water, and, as the annual consumption of milk in New York city and vicinity is 120,000,000 quarts, 40,000,000 quarts of water are used to dilute it, which, at ten cents per quart, cost the citizens $4,000,000 per annum, or about $12,000 per diem.

THE GLYCEROLE OF IODINE.—This preparation, recommended for loss of voice, is composed of a solution of 16 grains of iodine in one ounce of inodorous glycerine.

Lecture V.

PROGRESSIVE CEREBRO-SPINAL SCLEROSIC PALSY.

Definition — When and by whom made a distinct pathological species — Clinical History — Varieties of; cerebral form; spinal form; sometimes associated with locomotor ataxy — Duration — Prognosis — Patho-Anatomy — Histological Changes — Differential Diagnosis; from shaking palsy; from the paraplegias; from locomotor ataxy — Treatment. (*With six Engravings.*)

In this lecture I shall ask your attention to a disease of the cranio-spinal system of high interest, and which is attracting much notice. When on the subject of shaking palsy I spoke of it, and told you that until quite lately it had always been confounded with that affection, but really they were clinically and pathologically unlike. The French writers have named it, after its univocal lesion, *disseminated sclerosis of the brain and spinal cord;* I propose to call it *progressive cerebro-spinal sclerosic palsy.* It may be described in brief as:

A chronic disease of the brain and spinal cord, at times of abrupt onset, but commonly of slow approach; sometimes preceded by dizziness, headache, and apoplectiform symptoms, but more often beginning with weakness in one or both legs, which extends to the arms, and passes after a while into complete paralysis, and may affect the muscles of the neck, lips, pharynx, and tongue; no constant derangement of the various forms of cutaneous sensibility; attended with tremor in the disordered muscles, happening only when any voluntary movement is made or attempted, and ceasing whilst the muscles are at rest; often nystagmus; later on cramps, spasms, and permanent contractions of the palsied limbs; of probable diathetic origin; progressive in its course; of fatal ending; the anatomical characters being patches or corns of sclerosis irregularly scattered in the white substance of the brain, and in the anterior and lateral columns of the spinal cord.*

Two cases of this disease were described by Cruveilhier, more than thirty years ago, in his *Atlas d'Anatomie Pathologique*, and its morbid anatomy accurately delineated. Since then occasional cases have been reported by German writers. But its nature was ill-understood, its history was obscure, and the main points of practical significance escaped recognition until it was made the subject of special study by Drs. Vulpian and Charcot, particularly the latter. The eminent physician of la Salpêtrière distinguished it from the other forms of palsy with which it had apparent kinship, linked the lesion with a definite group of symptoms, and established its clinical and pathological autonomy.

* The term *apoplectiform* is here used in contradistinction to that of *apoplexy*. In which the symptoms are the result of cerebral hemorrhage or softening. In apoplectiform attacks there remain no evidences of material lesion; they occur in many brain disorders, and not unfrequently in hemiplegia; and yet after death no fresh effusion of blood can be found. In the present state of our knowledge it would seem that the only diagnostic mark between these attacks and those of true apoplexy is thermic; in the first the body-heat is generally increased, and never falls below the natural standard; whilst in the latter there is always at the beginning a lessened temperature.

Seizure may be sudden, the patient becoming instantly paraplegic, or vertiginous and hemiplegic. Again, considerable loss of power in the lower extremities during convalescence from an attack of typhoid fever or cholera may happen, which persists and increases, and proves to be the starting-point of the disease. But in a large majority of cases the invasion is gradual, muscular failing being foretokened by signs of nervous irritation, as numbness, tinglings, coldness, heaviness, and a sense of fatigue after slight exertion, in the legs. There may be some stiffness in the joints, making the movements awkward and constrained. When the brain is early implicated there are, foregoing or following the motorial troubles, spells of headache and dizziness, with faulty speech, and weak sight, and sometimes diplopy. But the lessening of motor power, either in one or both legs, is the fundamental initial symptom. This paresis may be regularly progressive from the beginning, or it may for a while remain stationary, and be so slight as to be only annoying after physical or mental exertion; or, and still more rarely, it may temporarily abate. Generally, however, in a little time the gait becomes uncertain, there is a tendency to trip, particularly in meeting with any unevenness of surface. The course of the paresis should be noted; if at the outset one leg only is affected, say the left, after a while the right will begin to fail; then probably the left arm, and afterwards the right. Sooner or later it deepens into complete palsy, the unfortunate patient becoming first paraplegic and afterwards losing all power in his upper extremities, the paralysis becoming generalized by following the same line as the paresis.

Now, sometimes coincident with the paresis, but more frequently later on, comes another symptom; a fundamental one, and one indeed by which the diagnosis is established; I mean tremor. Before this phenomenon is actual some unsteadiness in co-ordinated muscular acts may be observed. Its appearance, though inevitable, is uncertain and very variable, and often difficult to fix, because at first it may be so slight and occasional as to be hardly noteworthy. It may occur three months after the onset, or not for ten or fifteen months, and there are some reported cases where the paraplegia preceded it several years. In such the patient is already bedridden when it appears, and unless it is sought for and provoked it is pretty sure to be overlooked, and for this reason, that it *only happens when there is a volitional muscular act; it is always absent when the muscles are in a state of rest.* This is its diacritic feature, and it is a clinical fact of the utmost significance for us. It gives the disease its special physiognomy, like the characteristic gait of locomotor ataxy. As a rule, the order of the tremor is the same as that of the paresis. The kind or type is a series of rhythmical twitchings (secousses) or short snatches, which at first are mild, and do not hinder the common functions of the limb, but only qualify their mechanism. In raising a glass of water to the mouth, the gesture is not continuous and co-ordinate, but jerking and ill-regulated; the control of the will over the muscular effort is manifestly faulty; the hand is carried in various ways before the object is accomplished; or, from the violence and persistence of the jactitations, the act may fail altogether. The limb-tremors are usually in the direction of extension and flexion, sometimes in that of ab- and ad-duction, and occasionally in that of rotation. The head nods, rolls, or partially rotates; and the motion of the jaws is lateral.

About this time other symptoms are noticeable; the eyeballs begin to rock. The nystagmus is always

binocular; I know of but one exception. It usually occurs only on using the eye in trying to fix an object. When the tongue is protruded it is tremulous; speech is drawling, measured, and sometimes slightly thick, each syllable is pro-noun-ced sep-a-rate-ly, scanned, so to speak. Pain-spells in different parts of the body, as the limbs, trunk, and face, may be felt, the sight-troubles worsen, and the ophthalmoscope shows atrophy of the discs. So long as the patient remains sitting or lying, or in other words is perfectly quiet, there is nothing peculiar in the appearance; but the moment he is spoken to, or he tries to execute a given movement, the trembling begins. In a type-case you will see the head, arms, hands, legs, and muscles of the trunk all set violently a shaking in a moment. An attempt to drink will make the head tremble, or even raising it from the pillow. In the erect position a series of oscillations take place, the equilibrium being maintained with difficulty, and the body swaying in all directions.

Cutaneous sensibility, as respects touch, pain, temperature, tickling, in many, perhaps in most, cases remains undisturbed throughout; but this depends, of course, upon the district of the cord that may be damaged. In some cases darting pains in the limbs are felt; and a sensation of constriction about the waist—a stock symptom of the defunct classical chronic myelitis—is not uncommon. The body heat is natural, except there be intercurrent disorders; the pulse is often quickened, as in posterior sclerosis of the cord (locomotor ataxy).

At a latish stage of the disease, and not before paralysis is fully established, new phenomena in the muscular series occur; one or both lower limbs become suddenly rigid, resisting any effort to move them. These cramps are often attended with great pain, and when they have passed there is a feeling of fatigue in the limb. Temporary and recurring, they may last from a few minutes to several days, and in time are replaced by permanent contraction of the extremities, particularly the inferior. This follows strictly in its development the line of attack of the palsy, striking first the legs, then the arms, and sometimes the muscles of the trunk and jaw. Besides these, muscular spasm-spells may happen—the spinal epilepsy of Brown-Séquard—in which the legs are jerked about as if excited by a series of electric shocks. When of less degree they are like the muscular startings after the use of strychnia. If they occur before motility is quite abolished, they may alternate with the cramps. In some patients reflex movements may for a long time be provoked by pinching the skin of the legs or tickling the soles of the feet, whilst in others these excitations are without result.

The course of this disease is in a majority of cases regularly progressive. Muscular enfeeblement, as we have seen, slowly but surely increases, until there is more or less complete motor incapacity. Tremor, at the outset slight, partial, and occasional, is started by the least voluntary movement, and becomes violent and generalized. Convulsive agitations, spells of rigidity, and permanent contraction of the disabled limbs follow. The patient is condemned to his bed, lying all in a heap, an inert, helpless mass, with the legs forcibly flexed on the thighs, the thighs on the pelvis, and the heels drawn close up under the buttocks. Finally, the general health fails, nutrition becomes defective, and there is rapid emaciation. The muscles of the mouth and pharynx are paralyzed, and the mastication and deglutition of solids, and even the swallowing of liquids, are difficult or impossible. The saliva accumulates in the mouth, or dribbles out of the corners. Sloughs form on the parts of the body exposed to pressure, and may give rise to ascending secondary spinal meningitis, which proves fatal; or the patient dies from exhaustion; or, what is very common, death happens from some intercurrent disease of the lungs, or from erysipelas, or apoplexy. There are a few exceptions, however, in which the course of the disease was not regularly onward. There were remissions and pauses, and both the tremor and palsy greatly lessened, or for a time totally disappeared. But its progress is usually such as I have just described it.

I have endeavored to give a picture of this species of palsy in its type-form; but depending as it does on certain tissue-changes of invariable histological constitution—a special lesion of the nervous centres—the functional expressions of the morbid condition are determined by its exclusive or predominant possession of one or more districts of the cerebro-spinal axis. Hence there may be modifications of symptoms according to territorial distribution, and the occurrence of *varieties*. A cerebral form has been admitted, but it is supported, so far as I know, by a single observation, that of Valentiner and Frerichs, and is so doubtful from the unsatisfactory examination of the cord, that it ought to be rejected. It is possible that sclerous patches might be limited to certain parts of the brain without occurring in the spinal cord, but I have not been able to find any authenticated case. Not so, however, with the cord; many cases are recorded in which the morbid process did not extend beyond the cord; in this country we have the well-known case of the late Dr. Pennock, my predecessor in the Philadelphia Hospital. In such the cerebral phenomena are absent. Multiple sclerosis may involve not only the anterior and anterolateral columns, but also the posterior columns, and in that case the phenomena of locomotor ataxy—the lightning pains and motorial incoördination—are added to those proper to the spinal or cerebro-spinal form of progressive sclerosic palsy.

The average *duration* of progressive cerebro-spinal sclerosic palsy may be stated at from eight to ten years. In 17 fatal cases, it lasted 2 years in 2, 5 to 10 in 9, 13 in 2, 17 in 1, 21 in 1, and 24 in 1. The ages of death in these cases were: from 25 to 30, 2; from 30 to 35, 2; from 30 to 40, 4; from 41 to 45, 2; from 46 to 50, 2; from 51 to 55, 1.

No instance of recovery has yet been reported; and in the *prognosis* the possibility of pauses in its course, already mentioned, should be borne in mind. It is well to remember, too, that they are but temporary, in order that delusive hopes may not be excited. We have the same thing in posterior sclerosis (locomotor ataxy); but in neither case is there any reason to believe that there is any improvement in the tissue-changes. Damaged nervous tissue not unfrequently resumes capriciously and inexplicably its work for a while. Charcot and Joffroy mention instances of apparent recovery from complete paraplegia in Pott's disease, yet on the patient's dying from some other disorder, they found the well-known lesions from compression of the cord.

This affection is essentially one of adult life. In 18 cases, 14 were between 26 and 36 years at the time of invasion. With regard to the influence of sex, we have no certain information. So far this form of palsy has been chiefly studied at the Salpêtrière Hospital, to which females are alone admitted. We need more data to decide this point. It has, as I have said, followed acute diseases, as cholera and typhoid fever. Amongst the many assigned exciting causes, the only one which seems to me to have any evidence in its favor is long exposure to humidity, as living in damp houses. There is nothing to support the influence of heredity.

We come now to the *anatomical characters* of this affection. A brief study of its patho-anatomy will, I think, make clear much of its clinical history, for you will see that many of the symptoms are a natural outcome of the material damage we inevitably find in the nervous centres. Let us begin with the spinal cord. The membranes, as a rule, are healthy, and if there are any evidences of inflammation, it is recent — secondary ascending meningitis — and its cause the sacral sloughs. You may often distinguish through the pia-mater grayish spots here and there on the surface of the cord. Stripping off the membranes, these are found to be patches of an ashen hue, very much the color of the gray matter, oval in figure, irregularly distributed over several columns of the same side, or confined or nearly so to symmetrical columns; sometimes intersecting the fissures and points of emergence of the nerves; of variable dimensions, generally not more than about half an inch in their long diameter, and three or four lines in their shortest, though sometimes they are mere dots or grains, or a lineal streak or thread. Somewhat depressed, the tissue looks a little shrivelled, and feels firmer to the touch than the surrounding healthy structure, from which it appears to be sharply separated. In a few instances these patches have been found slightly prominent, turgescent, and less dense, probably indicating an earlier stage of the processus. On exposure to the air they acquire a rosy or salmon tint. On section through the cord at these points they prove to be irregular, conical masses, wedged into the white substance, the base of the wedge being on the periphery, and less in thickness than in superficial length; a glass of low power shows that they shade off into the healthy tissue, and that there is really no precise delimitation. Most often discrete, they are sometimes confluent. These drawings, representing sections of a sclerosed cord, will give some notion of their position (Figs. 1 and 2).

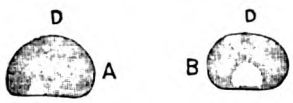

Fig. 1.

A, transverse section of the spinal cord above cervical enlargement; B, section in dorsal region; D, D, anterior fissure.

Fig. 2.

B, section in the dorsal region; C, the lumbar enlargement; D, D, anterior fissure.

Passing to the brain, we meet with the same lesion variously scattered through its several parts; but, as in the cord, they have here their points of election; when present in the brain, they are always found on the walls of the lateral ventricles, and on the floor of the fourth ventricle, a fact probably due to the vascularity of these parts. This constancy of site gives necessarily a uniformity of clinical history, and materially aids the diagnosis. The pons varolii is a frequent seat of the sclerous masses. Their most constant site in the cord are the anterior and antero-lateral columns, and in the medulla oblongata, separately or conjointly, on the olivary and restiform bodies and pyramids, but most often on the olivary bodies. This drawing shows a section of a sclerosed pons (Fig. 3).

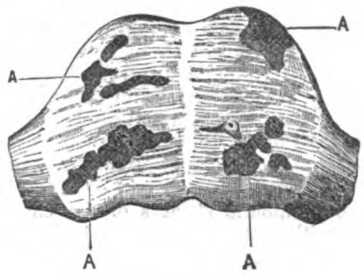

Fig. 3.

Section of the pons varolii.—A, A, A, patches of sclerosis on cut surface of upper portion.

In some instances one or several of the cerebral nerves have been affected; but with one exception, a recent case of Dr. Liouville, the spinal nerves have been free; the nerve roots are often to be seen issuing quite sound from the midst of a sclerous patch interesting a fissure.

In order that you may have a right understanding of the anatomical characters proper to cerebro-spinal sclerosic palsy, it will be necessary for me to say a few words concerning the perversions of the histological nervous elements in the several stages of the morbid processus. I shall do this as briefly as I can. By the term sclerosis we do not mean only "a thickening with condensation," as Virchow defines it. It involves textural changes both of quality and quantity, and includes creation, metamorphosis, and destruction. There is overgrowth (proliferation) and transformation, with consequent wasting of the proper elements of a part; in other words, histological substitution. Sclerosis of the nervous centres implies not only parasitic exuberance of the bed of connective tissue in which the essential nerve-structures lie, but proportional compression, deterioration, and mechanical annihilation of the ganglion-cells and nerve-tubes. These structural perversions necessarily bring functional perversions.

One word about the minute anatomy of the spinal cord. When a thin section, properly prepared in chromic acid and an ammoniacal solution of carmine and made transparent, is examined by a moderate power, a series of shining discs, with minute specks in their centre, are visible, which on close inspection are seen not to be in contact, but really separated by an apparently homogeneous substance, which fills up like a cement the interspaces. I have attempted to represent the appearance in this drawing (Fig. 4). These discs

[Fig. 4.

Nerve-tubes cut across—cylinder axis—neuroglia, or reticulum.

are the cut nerve-tubes, the light-colored spots their axis-cylinders, and the interspaces, less deeply tinted, the gangue or bed of connective tissue, called by Virchow the *neuroglia*, and by Kölliker the *reticulum*; and it is this connective tissue—neuroglia, or reticulum—which plays the chief part in the morbid processus we are studying. In it are the blood-vessels as well as the nerve elements proper. On its constituents the irrita-

ment, whatever it may be, acts; there is set up the morbid action; and the result are the tissue-changes which we recognize in the inevitable lesion. The consecutive phases and sum of these changes may be stated thus: First, overgrowth of connective nuclei and cells; second, development of fibrillary elements of great tenuity, resembling elastic tissue (fibroid substitution); third, compression and mechanical destruction of the nerve tubes; they lose their myelin casing, which undergoes granular disintegration, but their axis-cylinders, in a state of more or less integrity, persist; fourth, the lymphatic sheaths of the capillary vessels are filled with fatty granules, and their walls show nuclear proliferation. Sometimes these fatty granules accumulate in little masses. Occasionally we meet with a large number of amyloid bodies. Here are two drawings, copied from Dr. Charcot's microscopical examinations (Figs. 5 and 6).

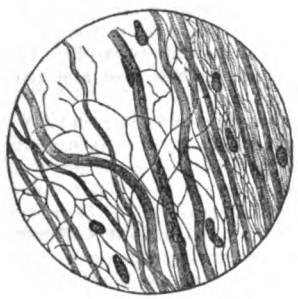

Fig. 5.

Recent preparation from centre of a patch of sclerosis of the cord, colored by carmine, and dilacerated.—In the centre a capillary vessel, with nuclei on its walls; on either side axis-cylinders, deprived of their myelin, some large, others small. Between the axis-cylinders delicate fibrils of recent formation are to be seen; on the left, nearly parallel to each other; but on the right they interlace and form a sort of irregular network. They may be distinguished from the axis-cylinders by their diameter, which is much less, their numerous ramifications, and by their not coloring by carmine. Scattered nuclei are also visible, some in connection with the fibrils.

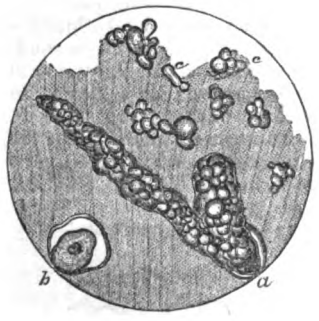

Fig. 6.

Portion of a patch of sclerosis from a recent cord.—*a*, lymphatic sheath of a vessel distended by large globules of fat; *b*, vessel cut across; the lymphatic sheath is separated from the tunica adventitia by an empty space, the globules of fat which distended the sheath having disappeared. *c*, *c*, little collections of globules of fat scattered over the field.

We meet with histological changes in the gray matter, and probably as we acquire more skill in our microscopical investigation of nerve-tissue, they will be found more constant than we have now the right to assert them to be. The nerve-cells undergo a peculiar alteration, known as *yellow degeneration*, from its ochrey tint, and in which state they no longer can be colored by carmine. We shall have occasion to study these changes more particularly when we take up some of the other progressive palsies. At present I shall only mention the fact, and point out its bearing on some of the symptoms we have noted, particularly the direct relation between the peculiar hesitating articulation, from damage to the nuclei at the origin of the hypoglossal and facial nerves which there is good reason to believe is quite constant; these points being, as I have said, one of the seats of election of the lesion.*

It must be owned that the *pathogeny* of this affection, as well as that of other kindred diseases of the great nervous centres, is obscure and unsettled. The problem is yet to be solved. I have elsewhere thrown out the suggestion whether we may not perhaps find a clue to a truer interpretation of their nature by admitting their connection with, and dependence on, some latent but definite condition of the constitution of the body which specially favors this peculiar form of morbid expression. That they are simply varieties of chronic inflammation of the brain and spinal cord, cannot, I think, be admitted. They are more than this. The causes commonly assigned for their production seem at most to be only extrinsic and exciting, and fail to explain their genesis, unless we admit some palpable pre-existing tendency. May they not then be local expressions of a general state in which a specific disposition enters as an essential factor? In sclerosis of the lung I have inclined to the hypothesis of a fibroid diathesis, original or acquired.† A careful study for some years of another form of sclerosis of the spinal cord—locomotor ataxy—has induced me to favor this theory of the pathogeny of the class of disorders under consideration. I believe if we had trustworthy statements of commemorative phenomena, we should find in all cases a foregoing stage to that recognized as the initial one, characterized by certain symptoms, as vague pains, passing spells of lessened muscular ability, etc. Is the sclerous processus in these disorders limited to the nervous centres? Is it not also going on simultaneously in some of the other organs? Is the pulmonary lesion, so frequently the immediate cause of death, tubercular or caseous, as generally stated? These are points of very great significance, and require for their solution a larger field of pathological experience than is usually the lot of one person. Many observations are necessary to settle the question, and I ask those who may have the opportunity to direct their inquiries to this end. Should the hypothesis of diathetic efficiency be borne out by clinical investigations, its practical value and application are clear, and it must necessarily bring about a change of treatment of a class of disorders which, we are now compelled to acknowledge, are uncontrollably and fatally progressive.

Progressive cerebro-spinal sclerosic palsy has sufficient individuality to secure generally its ready recognition. It is true that there always has been much confusion in the clinical history of the disorders of the nervous system in which tremor is a chief symptom, and diseases pathogenetically distinct have been treated of as one and the same. A study of this symptom shows that there are at least two kinds, differing in

* The reader who desires a fuller account of the histological changes is referred to *Notes on the Physiology and Pathology of the Nervous System, with reference to Clinical Medicine.*—New York: D. Appleton & Co. 1870.

† See article on "Sclerosis of the Lung," in Aitkin's Science and Practice of Medicine, 2d Am. ed., vol. ii., p. 763, by the Editor.

quality, and happening in distinct morbid groups. Galen noted and made the distinction between τρόμος (tremor) and παλμος (tremor coactus). Van Swieten speaks of tremor coactus, always present except during sleep, and tremor à debilitate. Of modern writers, Professor Gubler, in his excellent papers on the palsies (1860), recognized the two varieties, but failed to fix their clinical and pathological significance. Dr. Charcot was the first to establish their pathogenetic value. The want of a knowledge of this fact, and its proper interpretation and application, have led to the common mistake of describing this affection as paralysis agitans, or at least as a variety of it. But besides a distinction founded on the sure basis of pathological anatomy, there is really, when we come to analyze the symptoms of the two disorders, much clinical unlikeness. There is often some parallelism in the invasive stages. In both the approach is generally insidious; in both crawling sensations, numbness, and a lessening of muscular power, are noticed; but in shaking palsy these are almost always first felt in the arms, whilst in sclerosic palsy they are nearly constantly complained of in the legs. In the latter, the weakness in the limbs is the first motor symptom, and usually it is not until it has deepened into paralysis that tremor appears, and that may not be for years after seizure. In the former, tremor is an early symptom; motor debility does not perceptibly increase, at least for a long while. The trembling is incessant, and only interrupted by sleep or chloroform; it is but little modified whether the patient is at rest or in motion. The tremor of sclerosic palsy is never, as we have seen, spontaneous; it is invariably provoked by voluntary muscular action, by expenditure of nerve-force, and absolutely ceases when the muscular system is at rest. Another symptom, of the same order and mechanism, nystagmus, is frequently present in sclerosic palsy, and is never met with in paralysis agitans. The gait in the two diseases is eminently diacritic. A patient with shaking palsy, after the customary balancing and oscillations of the body, starts with the head and trunk bent, and trots and capers along, on the forepart of his feet, at almost running speed, with his arms semiflexed, and closely pressed against his sides. In Charcot's disease, the paraplegic shuffling gait is modified by the continual muscular snatches. There is at first titubation or staggering; afterwards, when muscular power is more faulty, the lifted leg is projected, not in a direct line from behind forwards, but the foot describes the arc of a circle, at first from within outwards; and when it reaches the extreme point of the curve, it is thrown inwards, coming to the ground with a flap, the sole striking the surface plump; at the same time there is a cadenced oscillation, an exaggerated alternate semi-rotation, of both sides of the pelvis. The facial expression is different in the two diseases; the patient with shaking palsy has often a senile, imbecile, or besotted look. Nothing of the sort is met with in the organic disease. The peculiar, measured articulation of a sclerotic is very different from the broken, jerking utterance in shaking palsy, somewhat like that in an ague-fit, or of a person unaccustomed to riding, who tries to speak when his horse breaks into a trot, and his words are ludicrously bumped out. The special deformities of the hands in shaking palsy cannot be confounded with the permanent contractions occurring in the terminal period of cerebro-spinal sclerosis. Finally, paralysis agitans is a disease of old age, whilst sclerosic palsy is one distinctly of middle life. We see, when we come to analyze the symptoms, how great is their unlikeness; the physiognomy of the two diseases is strikingly dissimilar, and it is surprising that the differentiation was not made long ago; or, indeed, is so little known even now. The importance of establishing the differential diagnosis as regards prognosis, must be my apology for dwelling so insistently upon it.

From the several forms of paraplegia its development, course, and the presence of tremor will generally serve to distinguish it. Some points of contact which this palsy has with general paralysis will be more appropriately noticed in my lecture on that subject.

When the posterior columns of the spinal cord are likewise affected, a condition I am disposed to think which happens more frequently than is generally admitted—forming those anomalous and puzzling cases of locomotor ataxy that have been recorded, and which we meet with every now and then,—when this happens, the symptoms are necessarily blended, and one set or other is predominant according to the district of the cord most damaged, and we have to separate them by careful investigation and analysis.

I can, unhappily, say nothing encouraging about the *treatment*. Of the various remedial measures that have been tried, none seem to have had the effect of even modifying the course of this cruel malady. Some of them, as the chloride of gold and phosphuret of zinc, have aggravated the symptoms. Strychnia will moderate the trembling, and nitrate of silver will do the same, except after permanent muscular contraction has set in, and then it does harm. If the views as to the nature of this and other sclerous disorders which I have suggested be correct, we shall probably be able, when detected in the early stages, to at least prevent their development, and, perhaps, even later on, to arrest their progress. I would recommend you to unite in the treatment of this form of palsy eliminating and nutritional means,—and whilst you use packing, and hot-air baths, and dry-rubbing—a daily grooming of the whole surface—and iodide of potassium, and the muriate of ammonia, try sulphur baths, arsenic, tonics, and a generous diet, in which fat enters as a large constituent; in other words, endeavor to rebuild a decaying nervous system. In giving you this advice I am satisfied that it is founded on just principles, and is the only one which promises any chance of success; but this I do not warrant. You must have perseverance, and your patient faith, and both recollect that chronic diseases require chronic treatment.

I am well aware of the difficulties you will have to encounter. You will meet not only with those inherent from the unpromising nature of the malady, but others extrinsic and circumstantial, and quite as formidable and discouraging. Some of your cases will have passed the period of possible recovery; many will be of a class, which either in their homes or in the public institutions where they may come under your care, cannot have the dietary and hygienic treatment which are indispensable to even conditional improvement, whilst those whose surroundings are more happy will be unwilling to undergo a tedious probation, with no speedy evidence of amendment; such become wearied and impatient, and hearing of this physician or that quack, or of some nostrum guaranteed by officious friends, flutter from one to another, tarrying yet a little while with each, until, after being drugged and promise-crammed, comes the true beginning of the end, and they are no longer masters of their fate. It is better to be frank with your patient, or his relatives, at the outset; explain as far as possible the real nature of the case, and the only possible means that may arrest its progress. If you fail to gain his or their

confidence, a happy issue can hardly be hoped for; but you will have done your duty both to him and to yourself, and you will eventually be better off than if you had inconsiderately deluded him with false hopes.

Original Communications.

IS THERE ANY THERAPEUTIC VALUE IN THE SO-CALLED "LOCALIZED MOVEMENTS?"*

By CHAS. F. TAYLOR, M.D.

MR. PRESIDENT:—

Some, perhaps most of the gentlemen present, may be aware that several years ago I devoted much attention to, and wrote several papers upon, the subject of the curing of disease by a kind of exercise or "movements." Now that it is generally known that I am devoting my attention wholly to orthopædic practice, I am often asked what my views are in regard to the therapeutic value of the so-called "localized movements." Although for the last half-dozen years I have been endeavoring to withdraw my attention almost entirely from the class of cases indicating this treatment, I have still been obliged to take and to treat numbers of the most characteristic of these cases; so that I have continued to have experience in the matter of such a nature as enables me to pronounce a positive opinion as to the value of the treatment under consideration.

I have been accustomed to use the term "localized movements" as being the nearest expression to the exact facts which I could find; and especially for the purpose of distinguishing certain so-called "movements" given or caused to be done with an idea of accomplishing certain definite results, from the general term *exercise*, with which they should never be confounded.

At the same time I desire to repudiate the idea which has been claimed by some, that there is anything empirically curative in any particular *movement* of itself, except as it may be physiologically calculated to correct some functional disturbance. When given for that purpose, based upon careful diagnosis, responsive to clear indications, and capable of effecting in any degree the result aimed at, then such movements are *not* exercise, *but* a treatment, and may be spoken of as such.

It is well, in the beginning, to have clear conceptions of what *is* exercise.

We all know that many diseases and derangements may be helped or cured by exercise. We may very properly regulate the degree, the time, and the manner of this exercise, according to the conditions, the capacities, and the general indications of our patients. In this way we may bring to bear a very large amount of experience, intelligence, knowledge of disease and constitution, and, above all, of *tact* in the management of patients; and they may thus derive an immediate and vast benefit from following our advice. But this is quite a different idea from that of making a direct medical agent of certain movements.

I have just said that there is no special medical effect, in the occult sense, in certain movements. It is only when they respond to indications, *and are capable of answering those indications*, that they become remedial in the sense of which I am speaking of them now.

Exercise, regulate it as you will, is, and must be, more or less general; the same as diet, though properly the subject of regulation, consists still in the administration of ordinary food. But when certain substances, such as iron, phosphates, and so forth, are prescribed because they contain the elements of substances supposed to be lacking in the system, then that would not be dieting, but medical treatment.

The fact is, we do not use movements for any of the purposes for which exercise is prescribed, but they are made to respond to a quite different class of indications. In exercise the initial expenditure of power is of the nervous force. The muscles obey the will. The will is brought into primary action; it commands, and the muscles obey. From the very nature of the case, there must be a general harmony, and more or less equality of action, between the nervous and the muscular systems. In an exercise, the first thing to be done is to make an effort; the will is brought into play, and the muscles respond in the direct proportion to the volition. There is throughout—no matter what you do—a constant and uniform reciprocal relation between will and muscular action. We find that there is a constant correspondence in the amount of expenditure of force between the nervous system and the muscular system. In other words, our muscular action depends entirely upon our volition. In fact, the volition is the initial process, and always corresponds to the amount of muscular effort which we wish to call forth. Under ordinary circumstances this is all that is necessary; the blood is circulated, the waste is carried off, the secretions are stimulated, interstitial change is effected, and so far as health can be promoted by effecting these alterative changes, so far exercise is all that may be required. But when we have a disturbance of the relations between the nervous and the organic systems; when, in fact, the volition and the muscles are thrown out of regular correspondence; when we have irregularities, with disproportionate loss of force in the one or the other, then the ordinary results of exercise which follow under other circumstances are not obtained.

Where, for instance, the person is already exhausted by over-taxing the brain, the indications for increased muscular action may be ever so strong, but we cannot secure the same result by exercise as we could if the brain and nervous system were not in this state of exhaustion.

The volition necessary to the exercise produces a much greater expenditure of nervous force, with a much less effect upon the muscles than it does in a well-balanced condition. In fact, under such circumstances, effort still further exhausts the brain-force, already too much drawn upon, while the muscles respond less perfectly than usual; so that the result is not refreshing nor invigorating, but may only add to the general exhaustion. But we must always recognize the general fact, that effort to an exhausted person, even effort of the muscles to a person exhausted by brain-labor, produces and can produce nothing but increased fatigue, because there can be no action of the muscles without a primary action of the brain.

Regulate it as you may, there is always the essential feature that the brain labor in securing the action of the muscles in all general exercise bears a certain ratio to this muscular action. Now the ratio of the relative expenditure of force, both nervous and muscular, varies with the temperament, health, state, and habits of the individual. As in laborers, for instance, where the muscular system preponderates, a large amount of muscular force is put forth by a relatively feeble volition, while in other cases, where action of the brain and nervous system preponderates, a great mental effort effects but a small exhibition of muscular

* Read (by request) before the New York Medical Journal Association, May 20, 1870.

force. It is this relative condition of the brain and nervous system, exhibited through volition as compared with muscular action, that "exercise" has no power to regulate or alter, and which furnishes the chief indication for the "localized movements" as a means of cure. By the term "means of cure" I do not intend the alterative effect which may be produced through the organism by general exercise. Increased assimilation, secretion, and muscular power are important considerations, as will subsequently appear, though important in a subordinate and special sense; but the primary idea of the movement cure is the control of the manifestations of the *nervous* system, which this treatment, rightly understood, places in our hands. We use the muscles, not because we care for them or desire to increase their strength,—this is not our idea,—but we use them as a kind of balance-wheel to regulate nervous action everywhere. This is our first and all-important consideration. The second and lesser idea in this treatment—the producing of *local effort*, in contradistinction to the general condition now under consideration—will be spoken of further along. The fundamental basis of the movement cure rests, then, upon the preponderating action of the brain and nervous system; and it is when the brain, stimulated by the intellect and will, and the cerebro-spinal system, continually excited by the temperament, the emotions, and æsthetic sensibilities, keep up the preponderating expenditure of force, and thus habitually subordinate the organic manifestations, that we need, and must have a treatment which recognizes this condition of things, and endeavor to correct it. It is a condition incident to civilization, and resulting from the intense strain brought upon the nervous system in the higher intellectual and emotional developments.

This condition is relative rather than positive; and still keeping up the comparison between voluntary effort and the using of the muscles as a therapeutic means, it is readily seen that to remove the organic system from its subordination to the greater activity of the nervous, we must institute different conditions from those of ordinary exercise, because I have previously shown that exercise, so-called, involves brain-labor in proportion to the muscular action, without regulating it. Now, the primary idea of the movement cure is to regulate and remove this relatively disproportionate action between the nervous and organic systems. Let me illustrate.

If a person, intellectual, with active brain, an emotional, sensitive temperament, and with corresponding and resulting muscular and organic feebleness, in consequence of some functional derangement be required to exercise in the gymnasium, or to ride or walk, or row or do any voluntary thing, while there may be an increase of crude muscular power, we have done nothing to correct the relative disproportion. The action of the brain and nervous system still preponderates, and the dynamic and organic powers, though augmented, are still subordinated. We have not yet touched at the root of our patient's condition, to correct it. Now, on the other hand, we have it in our power to regulate, not only the use of the muscles, how much, and the quality of the force called out, but we undertake to regulate the expenditure of the nervous force also; determining the amount and quality of the volition as well as the general condition of nervous repose and excitement in such a manner as, while increasing muscular action, we lessen the innervation required to produce it.

We would thus realize the primary object of the movement cure. It is not muscular action alone, nor is it muscular action under control, but regulated muscular action with the nervous manifestations under control. It is the use of the muscles with the nervous system in subordination. It is a temporary preponderation of the animal life through the muscles in the manner above mentioned, for the purpose of depressing nervous action and permanently exalting the organic power. We attempt nothing less than a positive change of temperament, whether natural or acquired, and realize our results only by securing more or less of such change of temperament.

Any one who supposes that the utility of the movement cure is comprised merely in manipulations or vibrations, or that it is only a better form of exercise; and especially any one who supposes that it consists of *passive* motions *very* good to amuse delicate ladies and hypochondriac gentlemen, has no just appreciation of the capacities of this treatment. I have no faith in the curative value of passive motions, vibrations, and manipulations when used alone in the class of cases now under consideration. The chief use of kneadings, rubbings, and passive movements generally, is to assist, by their agreeable quieting influence, in keeping the patient as free as possible from nervous irritability and mental excitement, until the curative treatment can take effect. And the distrust in the efficacy of the movement cure, which is wide-spread throughout the profession, is mainly due to the failure on the part of physicians to appreciate the existence of a psychological as well as a mechanical element in its employment. In this particular they have forgotten that any treatment, to be successful, must be based upon scientific knowledge as well as mechanical skill; and consigning their patients to the care of ignorant manipulators, they have been too prone to ascribe their failures to the apparent worthlessness of the treatment by localized movements (which in reality has not been practised at all), rather than to their own ignorance of the principles which underlie its proper application.

If we undertake to treat a case regardless of the basis I have pointed out, we shall be likely to fail of success. If the treatment be given while the patient is fatigued, or excited, or irritable, or when the mind is occupied, or the emotions are active, we can accomplish nothing.

The first step, then, in this treatment is to secure the voluntary control of the patient. This is always the most difficult as well as the most essential part of the treatment.

The intelligence, the feelings, and the emotions are on the *qui vive*, ready to spring into superior activity on the slightest provocation, or without a provocation, and it is just here that the patient is not in the habit of exerting self-control. Nevertheless, it is necessary that at the very start we establish complete voluntary control of our patient,—directing her thoughts and feelings, influencing the judgment, allaying apprehension, and in this and other ways placing her nervous system in a state of temporary repose, as the essential condition for beginning the use of the muscles in any curative sense. But when once we have instituted the using of the muscles, while the nervous system is thus tranquillized and subordinated, then the effect is to still further tranquillize. Muscular action, under those circumstances, produces the effect of a counter-irritation to the nervous excitability. In other words, the nervous force is husbanded and increased, with a corresponding diminution of irritability.

It is thus that hyperæsthesia is allayed, whether local or general. Morbid sensations and distresses, backache, dyspepsia, dysmenorrhœa, and hysteria, are evils of our day. They cannot exist in the exaggerated form affecting our women, except as a result of

their too active brains and too excitable temperaments, nor ought we to look for permanent relief without changing the condition which makes such suffering possible. This is precisely what the treatment under consideration proposes to do. It will be observed that we attempt to establish a more just relation between the nervous and organic forces by first establishing a voluntary subordination of the patient to the physician, and while in this condition of temporary repose of thought and feeling, to exalt the organic powers through the use of the muscles. We thus equalize the different manifestations of force and positively increase both. We have done more. The evil of nervous excitability is nervous waste; nervous waste long continued is debility, and debility begets irritability. Hence general and local hyperæsthesia and the long train of functional derangements which characterize the present age, and are admitted to be an opprobrium to our craft. Do you not see that a treament, starting with the proposition of preventing undue waste of nervous power and of equalizing the various manifestations of force by exalting the depressed organic powers, proposes also to cure many of the functional disorders,—the backaches and dyspepsias, the dysmenorrhœas and the various hyperæsthesiæ of modern society? And such I firmly believe this treatment, rightly understood and applied, is capable of doing.

But such results those who do not appreciate the psychological element in the treatment, but suppose it is comprised in certain twistings, rubbings, and stretchings, never will realize. The physician's earnest personal presence and influence is absolutely essential as a part of the conditions of treatment. It will be seen that the patient's active co-operation and support are also necessary. The patient must not be merely a passive party; she must not only comprehend the object of the treatment, which should generally be explained to her, but she must accept it, or she can never command the will to put herself in the state of temporary tranquillity necessary to the initiation of the treatment. If she oppose, and even if she give a *seeming* adherence to your requirements, it will be of no use. Reject the case at once. Whenever a patient comes to me who will not actually fall into the way I wish her, I send her home by the first train. After I find out there is any mental reservation in submitting to be controlled, I stop the useless, because one-sided, effort. The second, as it is the secondary, consideration already hinted at in this treatment, is the control of local function which it gives us. Hence the term which I have chosen as appropriate—"Localized Movements;" that is, movements given at one point for the purpose of producing an effect in other more or less distant points. We here also keep up the broad distinction between the movement cure and any species of exercise. To illustrate: We put the feet in warm water instead of giving a bath over the whole body for the purpose of warming the feet and removing sanguineous pressure in the head. We may also use the muscles of the feet or lower extremities, *while all other muscles are in repose*, for the same derivative purpose. We use a pill of aloes and nux vomica as an enema because they act only on the lower bowel. We may also use movements which act here and nowhere else for the same local purpose.

We use emmenagogues. Movements may be given more sure and powerful than any or all emmenagogues put together. To control the circulation is often to cure our patient. If we put the muscles of the extremities into gentle, firm contraction without accelerating the action of the heart and lungs, the blood flows into the extremities by the natural law of superior attraction in that direction, which it could not do if the action of heart and lungs were quickened so as to hinder the outflowing current, if not turn it inward, as may be the case in voluntary exercise in invalids. Thus we have the means of regulating the circulation. These are only a few instances. I will only just mention the obvious utility of localized movements in cases of muscular weakness and deficiency, or stiffening of the joints, &c. But the value of the treatment here, though important and more obvious at first thought, is yet of a lower order, and really of insignificant consequence, compared with that which it has been my design to explain and illustrate in this paper.

I have purposely refrained from saying anything in regard to the various means and methods of utilizing the treatment, because after all it is less important what you do than is the principle on which your procedure is based. My design has been to show that the treatment is founded on correct physiological conceptions, and thus scientific and legitimate. Legitimate only, I may add, like any other means, when in intelligent and honest hands. Because ignorant men have used and are using the term without knowing its true meaning, we should no more discard it, or the means it represents, than we should discard all remedies because charlatans sell nostrums. No treatment requires more judgment and experience, more careful diagnosis and the noting of indications, or needs more thorough knowledge of disease than the one under consideration. In fact, unless the physician possess these requisites he cannot understand or administer it at all.

Such, Mr. President, is a brief outline—a very brief outline, touching on one or two salient points—of the much-abused "Movement Cure," or the so-called "Localized Movements."

It has been set down in some quarters as one of the humbugs, and I as its chief apostle! I plead guilty to the apostleship; but if any gentleman can detect the humbuggery, he would confer a favor by pointing it out.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

Article IV.

MUSCLES OF SHOULDER AND HIP CONTINUED—OF ARM AND THIGH.

The belly of each pleurapophysis, usually concave, is filled with a muscle that acts upon the proximal extremity of the dependent limb; in the fore, this is called '*subscapularis*;' in the hind, it is known as the '*iliacus*.' These two are obvious and unquestioned homotypes. They occupy identical situations, have the same general relations, are inserted alike, and act correspondingly. In man, the iliacus exhibits the true functions more clearly than the other does; it is the short accessory flexor of the femur, aiding the long direct one (psoas magnus). Secondarily, it rotates the thigh outward, or 'everts' the limb, as the movement in question is called; that is, its trochanteric insertion enables it to throw the knee outward at the same time that the thigh is flexed at the pelvis. This latter action is really the prime function of the human subscapularis; which, by insertion into the tuber humeri minor, rotates the

bone inward,* or 'inverts' the limb; the subscapularis only secondarily, if at all, flexes (or retroduces) the arm. In both extremities this *flexion*, *i. e.*, retroduction of the humerus and anteduction of the femur, is the prime and main office of the two muscles; their rotatory action is secondary; but one and the other may in turn become the more prominent. The proper relation, preserved in the hind limb of man, is reversed in the fore, by the unusual shape and line of traction of the muscle. In most animals, the axis of power of the subscapularis is different, in consequence of the different configuration of the bony parts; in such, the muscle's function appears undisguised. We have frequent occasion to observe how slight a change of the line of traction may modify or even reverse the action of a muscle; and need be on guard to remove, when necessary, the teleological mask.

In man, the *teres major* is a considerable muscle. It arises from the first segment above the one it acts upon, and is therefore 'short;' it lies upon the back of the scapula, and consequently retroducts the humerus; it is the short direct flexor humeri, furthering the action of the 'long' flexor (latissimus dorsi). We search in vain for its antitype in man; in this animal, the corresponding muscle of the thigh has disappeared—presumably, because there is no occasion for its presence. But we find it in the first remove from man—in the anthropoid apes; and generally, in lower animals. It appears to have been first described in *Troglodytes niger*, by Traill; † and subsequently by Wilder; ‡ Owen § saw it in *Simia satyrus;* I ‖ found it in *Didelphys virginiana.* In the last-named, it is an insignificant muscle, lying upon the front of the hip-joint, in the position of, and comparatively about as large as, what in human anatomy is known as the 'ilio-femoral ligament'—the anterior accessory fasciculus of the capsular. Under whatever modifications of size and particular points of attachment, this is the muscle that repeats the teres major; in relative position, and in function (so far as it has any), it is precisely the short direct flexor femoris. Its large development in apes, etc., is probably in subserviency to greater ease in climbing, as indicated by the first name it received. This is a good illustration of the demand that must frequently be made upon comparative anatomy for determination of special homologies.

Three large muscles lie upon the scapular arch, each of which acts upon the proximal extremity of the humerus; these are, taken in order from before backward, *deltoid*, *supraspinatus*, *infraspinatus.* Three large muscles lie upon the pelvic arch, each of which acts upon the proximal extremity of the femur; they are, taken in order from behind forward (*i.e.*, in reversed or symmetrical direction), *ectoglutæus*, *mesoglutæus*, *entoglutæus*—in our 'specialized' and not always pertinent language, gluteus 'maximus,' 'medius' and 'minimus.' These are held to be homologous, each to the other, in the order indicated. They are very constant muscles in the mammalian series, and unquestionable morphological units. Their relative positions are closely kept, however they may vary in size, shape, and function.

In man, the only mammal in which locomotion is relegated exclusively to the hind legs, and in which prehension, etc., are committed to the fore, the deltoid and ectoglutæus are both at a maximum: no brute has such shoulder-pads, no brute such buttocks. In non-claviculate mammals the deltoid might hardly be recognized by physical characters, and may have intimate connection with the trapezius; in mammals generally, the "great" gluteus* is apt to be smaller than either, or both, of the others. The mesoglutæus is usually the largest of the three; from their peculiar relations it and the entoglutæus are often more or less blended. On the scapula, however, the 'spine' of that bone keeps the spinati distinct; their relative size is wholly a matter of the position of this spine. The functions of the six muscles in question are various—so various that no general statements will apply to every case—depending chiefly upon the shape of the shoulder-blade and haunch-bone; nothing whatever can be predicated of homology on this score. In man, the deltoid as a whole abducts; but its clavicular parts anteduct, and its scapular fibres retroduct. The great gluteal is slipped a little further back than the deltoid is forward; it extends and everts the thigh with abducting power in some positions of the limbs. In beasts with a long narrow pelvis it may be nearly a pure extensor (retroductor). It is purest abductor, when, as is often the case, it lies far forward, and comes straight down over the hip like a cowl, as, *e.g.*, the human trapezius does over the shoulder. In the matter of teleological modification, as where the category of a muscle, functionally considered, is to be laid down, physical configuration is a tyrant. In man, the function of the two muscles, as above given, is very nearly the same; and both are in part 'long,' in part 'short' extensors, etc., of their respective segments.† The morphological determination (which has been made of course without reference to function) is curiously borne out, in man, by certain physical characters; deltoid and ectoglutæus are both the *coarsest* muscles of the body.

If these two muscles, inserted so low down on their respective segments, vary so in function, it is impossible that the other two glutæi, and the two spinati, inserted at the top of the bones they move, should not be found to have actions so varying as to be totally indeterminate. A little difference in the shape of the scapula and ilium—a little variation in precise insertion—with change of position in the limb itself, give lines of traction that range from flexion, through rotation in different ways, to extension. This is a matter of observation, and need not be dwelt upon.

As already mentioned, the scapular spine keeps the two spinati apart; while the lesser glutæi, without such osseous septum, may blend. An analogous case, though one probably not offering homological data, is seen in the two fleshy bundles on the hind part of the human scapula: I mean infraspinatus and what is called '*teres minor.*' Perfectly distinct in this singular animal, the two form an indistinguishable mass in some others; or, at least, no teres minor is to be seen. The question arises, then, whether this be a morphological integer; and if not, to which of the two fleshy bundles it lies between is it to be referred? Almost certainly not, I think, to the teres major, which is quite another thing, as witness origin, course, insertion, action. If not a unit, it is a dismemberment, in some

* It should be observed that what is wrongly called 'inversion' or 'inward rotation' of the humerus is really an operation symmetrical with, and the counterpart of, 'eversion' of the thigh. In both cases, elbow and knee are thrown out or away from the axis of the body. The misnomer of the action in the case of the anterior extremity appears to have arisen from our looking at the two limbs as both pointing in the same direction, instead of opposite ones. This is so obvious that it must have been recognized; yet I have not seen the fact adduced. I retain, however, the customary mode of expressing the movement, as no change in names of muscles is involved.

† *Scansorius.* TRAILL. Mem. Wern. Soc. Nat. Hist. iii., p. —.(1818.)

§ *Invertor femoris*, OWEN. Proc. Zool. Soc., Lond. (1831.)

‖ *Ilio-femoralis*, COUES, Mem. Bost. Soc. Nat. Hist. (in press.)

* How far it may otherwise be modified, may be gathered from the fact, that in the *Ornithorhynchus* it extends to the bottom of the leg, and is connected with the plantar fascia.

† Sacral gluteus is 'long,' iliac 'short;' so, also, clavicular and scapular deltoid.

highly specialized animals, of the infraspinatus; all its relations, as well of origin as of insertion, and its functions, partake of those of the latter. It appears to have no posterior correlative; and could have none upon this hypothesis. If this view be incorrect, I have no idea to what muscle of the hind limb this inconstant one of the fore may be referable.*

Among muscles of the upper arm there only remain for consideration the *coraco-brachialis*, and *pectorales;* of the thigh, *pectinæus* and *adductores* (*brevis, longus, and magnus*). Taken collectively, the homotypy of these is obvious and unquestionable; but it is a matter of difficulty to determine which of individual muscles, or sets of muscles, in one limb, correspond to those of the other. Before stating the condition of osseous identification upon which the question of the muscles seems to hinge, as already hinted (Art. II., p. 194), and probably will finally rest, we may glance at some other points involved.

The *pectoralis minor*, as suggested (Art. III., p. 223.), is probably a humeral muscle, notwithstanding its coracoid insertion in man. In all birds, so far as I know, it goes to the humerus; in monotrematous mammals, next to birds, it may either be wanting, or else represented in one of the several divisions of the *p. major;* in higher mammals, it may go to the glenoid cavity; in those next to man, it goes indifferently to coracoid or humerus, or to one on one side, the other on the other, of the same *individual.* † Doubtless other facts could be adduced in favor of the view proposed. The pectoralis, then, or the *pectorales*, as the case may be, are 'long' humeral muscles, arising beyond the first segment above the one to be acted upon. They are powerful adductors of the limb, with also retroducting and rotating action. But this retroducting depends upon the greater part of the muscle being situated below the centre of motion; clavicular fasciculi may represent anteductors of the humerus, similar in action to contiguous portions of the deltoid.

The four corresponding muscles of the hind limb, above mentioned, may be regarded (taking an average of their several exhibitions in different animals) as a four-parted plane of adductors, that range from flexors to extensors according to circumstances, and have also rotatory action from their insertion in or near a 'linea aspera femoris.' In animals with a long narrow pelvis, these adductors become almost pure extensors (retroductors) of the thigh—especially the *add. magnus*, which is inserted lowest down. Only the uppermost or most anterior of the set are decidedly flexing in action; the pectinæus particularly. The last named is usually, if not always, more distinct from the three adductors proper than these are liable to be from each other; and moreover—what is to be especially remembered—it is essentially a *pubo-femoral* muscle;‡ while the rest, though arising in some or great part from pubis, are essentially *ischio-femoral.* Again: while in man the three adductors are perfectly distinct, they are not so in some quadrupeds; their origin may be side by side, their course parallel, their insertion *seriatim* in a line along the femur, and their relations of contiguity liable to be changed into those of continuity. It is sometimes difficult to tell which is which of the several subdivisions. It appears not improbable, therefore, that the three adductors represent a morphological unit. The pectoralis is found similarly subdivided in some animals.

It is obvious that we may argue either way in respect of particular determination of the several muscles in question; although on the whole, and especially taking position into prime account, it is more reasonably, probably, to be concluded, that the adductors represent the pectorales, and the pectinæus the coraco-brachialis. This view would be strengthened, if not demonstrated, should Wyman's identification of coracoid with pubis, and clavicle with ischium, prove the only tenable one. But at the same time it is to be remembered, that there are reasons for regarding ischium as coracoid, and pubis as clavicle; upon which hypothesis the converse determination of the muscles must be held. The latter is Wilder's view, and apparently, the grounds upon which it is based. I incline at present to that first given.

This finishes our survey of the muscles of the arm and thigh;* in our next we shall examine those of the forearm and leg.

* Wilder finds its correlative in the *glutæus minimus:* we are at one, therefore, in this respect, if the teres minor be a part of the infraspinatus, as I think. So we are, also, in respect of glutæus medius and supraspinatus, as correlatives. But he refers infraspinatus to *psoas magnus;* this I consider inadmissible, for reasons given in the last paper.

Finally, another view suggests itself: Let the two lesser glutæi and the two spinati remain as homologized in the above text, but the teres minor be considered distinct from the infraspinatus; then the teres minor becomes a possible analtype of the *psoas magnus.* We have only to regard it as slipped a little way from the belly to the edge of the back of the scapula—a sort of disintegration of the subscapularis, as the psoas magnus may be of the iliacus.

† Thus Wilder, Cont. Comp. Anat. Chimpanzee, l. c., p. 859:—The p. minor "is quite variable in its insertion, which is sometimes into the coracoid process, as in man, sometimes into the great tuberosity of the humerus; in this chimpanzee the former was the case on the left side, but the latter on the right side."

‡ In marsupials, the pectinæus arises even above the brim of the pelvis; *i. e.*, from the base of the movable marsupial bones.

* The *tensor vaginæ femoris* appears to be a teleological interpolation, for the better action of the great extensor of the leg. It is virtually a sort of extensor cruris, but really appears not to belong to the category of muscles moving the framework of the body. It occurs chiefly in higher animals. In birds, Owen considers it as included in the *rectus femoris* ("abductor magnus.") In the anterior extremity, nothing equal to it has been noted.

In many mammals there is a muscle of the humerus not found in man:—the *dermo-brachialis.* It is a cutaneous muscle, apparently a specialization of the *panniculus carnosus* of quadrupeds of which the *platysma myoides* is our remnant. It is like a duplicate or supernumerary latissimus dorsi, which it overlies; arising from the skin of the back, loins, sides, etc., broad and fan-shaped, converging anteriorly to be inserted in various ways in the humerus and elsewhere, usually with or near the latissimus. It seems to have no posterior correlative. But in one animal, at least, (*Ornithorhynchus paradoxus.*) the whole panniculus itself is disposed with nearly perfect symmetry. It begins on the tail, and ends on the head, and forms a complete muscular tunic, in which the animal is enwrapped, with legs and arms protruding through four oblique slits, all alike.

Progress of Medical Science.

New Instrument for the Operation in Fistula in Ano.—In a recent case of operation for fistula in ano, instead of the usual plan of introducing the bistoury through the fistula, and bringing it down through the sphincter, Mr. Weeden Cooke used a scissors constructed for him by Messrs. Weiss. The finger having been introduced into the rectum as a guide, Mr. Cooke passed one blade of the scissors into the fistula up to its extreme point, and then the other blade into the rectum. The two blades were then connected by a small screw, and by one rapid scissors action the sphincter was divided.

As the position required for this operation renders it unadvisable to give chloroform, and as the patient, unless very carefully held by assistants, often shrinks so as greatly to embarrass the surgeon, any plan which insures rapidity is advantageous, and it is with this view that the mode of operation described has been suggested. It was thought that it caused less pain than the bistoury.—*Lancet.*

The Pancreatic Ducts.—M. Claude Bernard, in noticing at the Paris Academy of Medicine a communica-

tion respecting pancreas, said that he considered that the canals discovered by the physiologist Weber are of uncertain use. They are extremely fine, and become visible only by injection. M. Legonis had found, after five years' investigation, that they were the excretory canals, and that they often constituted the entire pancreas. In many fishes the pancreas is altogether absent, but it is replaced by canals which receive the name of disseminated pancreas.

Preservation of Animal Vaccine Matter.—M. Warlomont, of Brussels, has addressed a letter to the Academy of Medicine of Paris, in which (although a thorough advocate for animal vaccination) he remarks that many of the objections to it are well founded. For instance, the animal vaccine matter cannot be preserved, for one hour's exposure to air destroys all its efficacy.

The director of the Royal Institution of Belgium has recognized the fact that it can be kept neither in tubes nor on glass plates. He has, however, invented a method for its preservation. M. Warlomont takes small ivory points and dips them in strong gum water. This layer being dry, he applies the vaccine matter taken from the heifer, and at once again applies a layer of gum.—*Med. Press and Circular.*

Uterine Hemorrhage Arrested by Heat to the Spine.—Professor Beneka, of Marburg, has arrested hemorrhage from the uterus in several cases by the application of heat to the spine. He thinks much can and will be done by the principle of applying cold and heat to the spine. As far as the heat is concerned, his experience has fully convinced him of its extreme usefulness in certain cases, reports of which he has kindly promised to send to us for publication.—*Med. Mirror.*

Intermittent Pulse.—Dr. Benj. W. Richardson (*Am. Jour. of Insanity*) has shown that intermittent pulse is a physical symptom of cerebral and mental origin. He has never met with a case in which the disorder was not sequential to some anxiety; shock, fear, sorrow, or their similars. He has met with case upon case in which the sufferer has been able, from his own perception of the intermittency, to register the precise moment when the injury causing it was inflicted.

Dr. Liveing on Skin Diseases.—The *Med. Press and Circular* furnishes the following brief synopsis of Dr. Liveing's recent work: Under the head of eczema, boiled water dressings are recommended locally, covered with oiled silk, if coolness is not required. The use of a lotion containing five grains of caustic potash to an ounce of water is advised in some chronic cases. Lupus is treated by acid nitrate of mercury, and solid nitrate of silver with cod-liver oil as a drug. In ptyriasis he recommended a mixture of white precipitate, and red oxide of mercury ointments locally. Prurigo in almost every case, he says, is due to pediculi. Heat the cloths and use stavisagre ointment. He recommends lotion of atropia in cases of pruritus, and application of nitrate of silver. Fowler's solution is recommended for psoriasis, and, in some cases, carbolic acid and copaiba; soft-soap and tar-ointment as local applications. In syphilis, he likes perchloride of mercury for secondary eruptions, and blue ointment for infants suffering from syphilis; sometimes iodide of potassium is preferred in secondary syphilis and tertiary syphilis as a rule. In fact, in this he seems to re-echo the opinions of M. Hardy. In tinea decalvans the bald spots should be blistered every fortnight by liquor epispasticus.

In favus a strong sulphurous acid lotion is recommended, and the hairs should be pulled out. In ringworm the hair should be cut short and the bald patch blistered with acetum cantharidis, and in some cases the hairs extracted. Ptyriasis and versicolor are easily cured by sponging the skin with sulphurous acid of the B. P. Warts are to be touched with glacial acetic acid, and blistering fluid sometimes will do; white-precipitate ointment is recommended for pediculi capetis. Scabies is treated by sulphur ointment, or sulphur and potash ointment, after the patient has taken a hot bath. Sycosis is treated by epilation.

Syphon for the Stomach Pump.—The *Deutsches Archiv* has published a paper by Dr. Jürgensen, of Kiel, which fully corroborates all that has been said as to the efficiency of a syphon to replace the stomach pump. The stomach may be readily emptied and as readily washed out by this simple mode. A sound has only to be placed into the stomach and its upper end attached to the short arm of a glass syphon by india-rubber tubing. The patient must then cough or retch, and the stomach, if full, will rapidly be emptied. Dr. Jürgensen employs this mode to wash out the stomach regularly with water, or with acid or alkaline liquids, in cases of gastric disease.

Purulent Infection and Erysipelas.—Dr. Lefort has read to the Medical Academy of Paris a memoir on the purulent infection and erysipelas, too frequent and too formidable complications after operations in nosocomial practice in Paris. The treatment of Dr. Lefort consists in covering the wound with one or several compresses steeped in a mixture of water and of 1-10th of camphorated spirits. It is necessary to excite the wound, he adds, in several proportions, according to the cases, by a solution of sulphate of zinc to 1-10th, and envelop all corresponding parts of the limb with a piece of oiled silk, maintaining it in place by several turns of a bandage. He takes care that the wrapping shall be compact and the wound hermetically sealed.

The evaporation of the liquid imbibed by the compresses not being affected, the product of the insensible evaporation over the surface of the skin being retained, the wound is in a kind of continual bath.

Without the inconvenience of a maceration, which softens the tissue and seems to diminish its vitality, without the weariness occasioned by the necessity of apparel difficult to employ, he obtains the advantages of the bath of Major, of Langenbeck, of Vallette of this city, or of the continual irrigation. The sedative action of the camphorated water, modified, according to the indications, by those of medicated solutions, tempers the inflammation and keeps it within the limits necessary to the work of cicatrization. The *pus*, sheltered from the permanent contact of the air, does not suffer any modification; it remains, it is true, in contact with the wound, but the result proves the innocuity of unaffected pus. The compress, not able to dry itself, does not adhere to the wound; it is loosened easily, and there is no fear of excoriation.

So all needful conditions of healing are obtained by this method: The shelter of the wound from the contact of the air, the modification of it—if it is necessary—by application of medicinal substances, the maintenance of the humidity of the wound, the impossibility of the decomposition of the matter, the perfect neatness of the wound, the non-adhesion of the pieces of decaying tissue, and the destruction of the germ which might be the point of departure of infection.

Dr. Lefort cites several cases, and gives some statistics which confirm his considerations and treatment in

drying up, also the action of this mode of treating diffused phlegmon.—*Med. Press and Circular.*

Consumption and Cancer.—Pulmonary consumption is derived from cancer, according to Dr. Burdel. This practitioner, from 100 cancerous parents, has seen seventy-five times pulmonary consumption reach the children, and he has seen fifteen times pulmonary consumption derived from other diseases.

The cancer, then, according to this new doctrine, comes immediately after pulmonary consumption itself in its power to produce tuberculous diseases in the following generations. It is so that out of 100 families who have furnished the cases of Dr. Burdel, 79 afflicted with cancer have produced by direct and secondary inheritance 237 tuberculous cases.—*Med. Press and Circular.*

Temperature of the Cranial Cavity.—The temperature of the cranial cavity has lately been made the subject of investigation by M. Mendel, of Pankow, near Berlin. Fick had already found the normal temperature of the cranial cavity to be lower than that of the body generally. Jacobson and Bernhardt had likewise noticed the inferior temperature of the blood arriving at the heart by the superior vena cava, as well as the depression it produces in the right cavities. M. Mendel corroborates these results, and finds constantly that in health there is a difference amounting to seven-tenths, or even to one degree centigrade, between the temperature of the cranial cavity and the rectum in the rabbit; and that in the dog the difference is almost as well marked. Duméril and Demarquay have shown that the temperature of the body is lowered by the action of chloroform. Bouisson arrived at the same results, as have also Sulzynski and Scheinnesson, the experiments of the latter having been performed upon man. The differences observed by Mendel between the temperatures of the cranium and the rectum are much more clearly marked when the animal is under the influence of chloroform than when in a normal state. Chloroform lowers the temperature generally, but especially that of the cranial cavity. The effects produced by chloral on the temperature of the body generally have been already studied by Demarquay. This author has found that the temperature of the body falls several tenths of a degree. M. Mendel arrives at the same results in regard to the temperature of the cranial cavity, except that he has observed it to fall to a still greater degree than the general temperature. Deguix, Dupuy, Leuret, and Gscheidlen have found that, after a moderate or therapeutical dose of morphia, the temperature of the body rises; though when administered in a poisonous dose it falls. Mendel again arrives at the same law—viz., that the depression of temperature is more marked, and occurs more rapidly, in the cranial cavity than in the rest of the body. In poisoning by alcohol, the temperature of the cranial cavity rises to such a point that it exceeds the temperature of the rectum.—*Lancet.*

Late Atmospheric Researches.—At a meeting of the Royal Irish Academy, held June 13th, Dr. George Sigerson, F.L.S., read a paper entitled "Further Researches on the Atmosphere." He stated that the results of analyses of *ordinary atmospheres*, such as those of the town, the country, and the sea-breeze, which he had communicated to the Academy on a former occasion, had been fully confirmed by later investigations. The subject of the present paper was the examination of *special atmospheres*, of which the author proceeded to speak in detail. In the air of an *iron factory* he found a dust of a black color and friable in nature, which was composed of carbon, iron, and ash. The iron was present in small rough and jagged pieces, and also in hollow balls averaging one two-thousandth of an inch in diameter. These iron globules were translucent. In *shirt-factory* air, filaments of linen and cotton were present in great numbers, and minute eggs were also seen under the microscope; but these were, perhaps, of accidental origin. *Scotch mills*, from the nature and quality of the spongy, spiky dust which abounded in them, Dr. Sigerson branded as human slaughter-houses. In the dust of printing-offices, perceptible traces of antimony were detected by chemical examination. *Stable air* was shown to contain equine hair, cuticles, epithelium, moth cells, ovules, various fungi, besides a large amount of other forms of organic matter. The air of a dissecting-room was also largely impregnated with organic particles, and a microscopical examination of the dust collected resolved it into portions of white and yellow fibrous tissue, fibrillæ of voluntary and involuntary muscle, fragments of epithelium, and *débris*. In *smoker's air*, numerous globules of hot nicotine were observed, of a pre-eminently hurtful character. Very similar to this was the air inhaled by *tea-tasters*, in which, besides particles of cellular tissue, a narcotic oil of very deadly properties abounded in the form of minute cells. In concluding his paper, Dr. Sigerson took occasion to remark that the carbon which existed in the atmospheres of large cities was of use in counteracting the injurious effects of the presence of albuminoid ammonia, lately described by Dr. Angus Smith, of Manchester, and that consequently limits should be placed to the consumption of smoke in factories, etc. The paper was illustrated by large diagrams representing the microscopical appearances of the different forms of dust spoken of above.—*British Med. Journal.*

Treatment of Typho-Cerebral Fever.—A. Given, M.D., Louisville, Ky. (*Chicago Med. Examiner*), in his able paper on "Typhoid Fever," treats the *cerebral type* on general principles, but early directs attention to the delirium or head symptoms; for without sleep the patient will die, and that speedily. He has found nothing so beneficial in controlling the delirium and promoting sleep as the following:—

℞ Chloroform		ʒ ij
Pulvis acaciæ Saccha. alba	āā	ʒ iij
Tr. Opii Deodor.		ʒ ij
Bromide Potassa		ʒ iv
Aqua Menthæ		℥ ij

Mix, and give a teaspoonful every two hours, until the patient is quiet. If the head is hot it may be frequently bathed with cold water. If the bowels do not move regularly, the enema of warm water and salt may be used from time to time.

Sir H. Thompson on Lithotrity.—At a meeting of the Royal Medical and Chirurgical Society, on May 10th, Sir H. Thompson gave the result of 184 cases of lithotrity in adults. The mean age of these patients was sixty-one, the recoveries 93 per cent., but, omitting five cases of death not due to the operation, the mortality was only four per cent. Lithotrity was an eminently successful operation; he had never lost a patient after crushing a stone no larger than a small nut. When employed for stones the size of a chestnut, a certain percentage of deaths may be expected. All calculi less than an ounce in weight should be crushed. Mr. Cadge, of Norwich, regarded the recurrence of stone as the weak point in lithotrity. It is difficult to get rid of the last little fragment, and if left the stone is certain to recur.—*Med. Press & Circular.*

CONTROVERSIAL PAMPHLETEERING.

FROM present indications, the profession are having a lively time in abusive discussion. Every one knows that we as a body have always been disposed to quarrel at the slightest provocation;—it is a fact of our social history established hundreds of years ago—but within the past year or two we have been more than usually belligerent. Not content with a simply oral adjustment of what are technically considered our individual rights, we are getting into the habit of washing our dirty linen before as large audiences as we can obtain. The arena of the society-room is exchanged for the pages of some medical journal; and not content with this publicity, reprints of these elaborate articles are made, which are mailed by the thousand to all the accessible and respectable physicians in the country. The pamphlet mania is getting to be something fearful. No sooner is the slightest difference between two medical men established, than Dr. A. considers it his bounden duty to expose the fraud of Dr. B.; when Dr. B., for the sake of *his* reputation, must reply, and pamphlet after pamphlet is thrust before the reader. So far as this may go towards the establishment of any scientific point, it is justifiable, and eminently proper; but who ever knew it to stop there? On the contrary, science is really the cloak for the bitterest personal animosity. This is evident enough in the personal manner in which these discussions are almost invariably carried on. It is apparent that the aim is not to avoid personalities, but to bring them in whenever a favorable opportunity offers, and at the same time to give just enough of scientific data to make the dose as palatable as possible.

If Dr. A. desires to expose Dr. B., let him do it as becomes an individual in search of the naked truth, but not as his implacable foe. Let him conquer him by scientific truths, not by unmanly insinuations, disgraceful epithets, and unbecoming language. If B. is crushed to the earth as a mistaken, misguided, and deluded wretch, who has spent his life in vain, and has learned nothing by experience, there is no real need of adding to this ignominy by posting him as a liar, or even as a thief. Yet this is done in more or less elegant and covert language in the great majority of the controversial pamphlets or reprints that are flooding the medical market. The punishment to the worsted individual is terrible enough when it stops at the imputation of utter ignorance of the ordinary principles of medicine. Is there really no mercy in these pamphleteers? Can they not consider the dreadful responsibility which belongs to the man who deliberately draws his quill against his brother, with the full appreciation of its terrible power? We believe if the majority of these writers really imagined the irrevocable injuries they were capable of inflicting upon their antagonists, they would be overcome with remorse. What if the pamphleteer does establish for himself the reputation of a satirist, a man of science, and a writer; can it counterbalance the terrible thought that the incontrovertible arguments he has used, and the incontestable facts which he has asserted, were the very thunderbolts of annihilation to his opponent? If the victor settles for all time the reputation of the vanquished one, he may be actually depriving him of a livelihood which otherwise he might obtain. Pamphleteers, think of this! In meting out your justice, remember mercy.

Another important point for the consideration of this class of writers is whether or not the profession at large really care at all concerning the great point at issue; whether the true *casus belli* is recognized. As most of these gentlemen believe these pamphlets excellent media for notoriety, it becomes them to seriously weigh this question, otherwise all their brain-labor, research, and lampoonery may be expended in vain. To such as are in doubt we commend the full benefit of the same, while to those who are confident that they can interest their audience we would suggest that a pamphlet of fifty printed pages is sufficiently lengthy to convince any unprejudiced mind; all beyond that being sheer waste of labor, printers' ink, paper, and brain-matter.

As the object of all such explanations is the elevation of the dignity of our common calling, and the establishment of strictly scientific truths, it is obvious that their circulation among the laity cannot be attended with any great benefit, save to the writers of the same. If any such persons may be tempted, as many have already been, to send copies of their pamphlets to the different public papers, they should first consider, as individuals, whether the profession, as a body, would be complimented by fathering the sentiments they may choose to utter.

Finally, we advise all those who wish to maintain the enviable reputation of gladiatorial pamphleteers to lose no opportunity for attacking everything and anything, and in each case be sure of the opportunity for one or two convincing, elaborate, and overwhelming replies; making it, at the same time, apparent to the reader that nothing but the pure love for science prompts them to continue the controversy. Who will

be the author of the next pamphlet, and who the fortunate respondent? We ask this question because are convinced that the end is not yet, and that many righteous individuals are only waiting for fair opportunities to call forth their special talents.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, JULY 7, 1870.

DR. H. D. BULKLEY, PRESIDENT, in the Chair.

"Foreign Bodies in the Air-Passages," illustrated by two rare Cases, by Gurdon Buck, M.D., Surgeon to New York Hospital and St. Luke's Hospital, &c., &c., &c.

THE following gentlemen were elected by ballot Resident Fellows of the Academy:—Drs. John C. Peters, Faneuil D. Weisse, Frank P. Foster, Harvey C. Gay, Wm. O'Meagher, and Theodore Walser.

DR. BUCK then proceeded to read the two following interesting and rare cases:—*1st. Case of fish-bone lodged in larynx during a period of fourteen years—trachea tube inserted after laryngo-tracheotomy and worn twelve years.*

On the 22d of May, 1855, Mrs. F. C. J., æt. 25, daughter of a physician residing at N. R., while eating small fish at dinner, had a bone lodged in her throat, which at once caused great disturbance and violent efforts of coughing and hawking to disengage the foreign body. Her father improvised a probang and passed it down the œsophagus, and resorted to various other measures for her relief, but without success. She could reach the bone on the left side of the throat with her left fore-finger and perceive that the end of the bone pointed upward. The same evening at about 9 o'clock, while taking some food, the bone became dislodged and complete relief followed, to her great joy and that of her family. For eight days she continued well, with the exception of slight remaining soreness, and then began to cough. As she had been somewhat exposed in a visit to the city, the cough was attributed to her having taken cold. Soon the cough became croupy and sonorous, and very frequent, especially at night. The voice began to be affected with hoarseness, at first only at night, when suffering from attacks of dyspnœa; subsequently, however, the hoarseness became constant. Suffocative attacks at night increased in severity, and sometimes were very alarming. The use of opiates at bed-time, such as Dover's powder, or McMunn's elixir of opium, became indispensable, and would often keep her easy for the night. There was nothing visible or tangible in the throat. Deglutition was easy. Sometimes she felt pain darting through the throat, and also soreness in a particular spot on the left side when pressure was made with the finger over the thyroid cartilage. The cough has been without expectoration from the first. July 7th, 1855, nearly seven weeks after the accident, Dr. Buck saw the patient for the first time, in consultation with Dr. Voris, her attending physician. The conclusion arrived at was, that Mrs. J.'s ailment was unconnected with the accident of the fish-bone. An application of leeches over the larynx, a mild mercurial course, alum emetics, and inhalations of vapor were advised and tried, but were followed by only temporary benefit. The mercurial was afterwards resumed and blisters applied over the larnyx. Anodynes were also given at bed-time. No permanent benefit followed; on the contrary, her condition grew steadily worse. Dyspnœa became constant by day as well as by night, and was aggravated by every exertion. The patient having come to the city, a second consultation was held on the 29th day of September, 1855, in which Drs. Camman, Willard Parker, and John Watson joined the original consultants. Each gentleman visited and examined the patient separately the day before. After a full discussion it was unanimously agreed that the origin and persistence of the symptoms depended on the presence of the fish-bone in or near the larnynx, and that a surgical operation was the only resource from which relief was to be expected. As the patient's general health was steadily deteriorating, and the suffocative attacks had become more frequent and severe, another consultation was held on the 7th January, 1858, in which Dr. Camman, Profs. A. Clark and Jos. M. Smith, as physicians, and Prof. W. Parker and Dr. John Watson as surgeons, took part with the speaker. After a free expression of opinion and discussion the following conclusions were arrived at:—

1st. That there was no evidence of tuberculosis or other disease in the lungs or elsewhere.

2d. That her condition is to be attributed to the continued presence of the fish-bone swallowed in the month of May, 1855; and inasmuch as a sore spot has uniformly been referred to the left side of the thyroid cartilage, and to a point corresponding to the situation of the left ventricle of the larynx, it is thought possible that the bone is imbedded in the ventricle.

3d. That inasmuch as no relief has been afforded by any medical treatment hitherto employed, a surgical operation is required, and should be resorted to without delay.

4th. That the operation of laryngo-tracheotomy is to be preferred in this case.

Operation.—On the 10th January, 1858, at 2 o'clock, patient was placed on a narrow bed facing a window, and the bedstead elevated at its head so as to form an inclined plane. Ether having been administered, an incision was made in the median line from the os hyoides to the third tracheal ring, and the tissues successively divided till the cartilages were laid bare. The hemorrhage, which was moderate, was allowed to cease before incising the larynx. The crico-thyroid membrane was first pierced in the median line, and the incision continued upward from the upper edge of the cricoid cartilage through the lower half of the thyroid cartilage. At this moment the air rushing in through the opening, the lungs seemed as though taken by surprise, and for an instant intermitted their action. In order to afford prompt and free access of air to the lungs, he immediately extended the incision downward through the cricoid cartilage and the two upper tracheal rings, and stretched the edges of the opening apart. As soon as the respiration had become quietly established through the wound, the upper half of the thyroid cartilage was divided very exactly in the median line through the notch. The next step was to make a thorough inspection of the interior of the larynx, especially of the left ventricle. The attempts to do this, by stretching apart the edges of the wound, excited a good deal of disturbance, such as coughing and suffocation, so that they were compelled frequently to desist, and allow patient to recover herself. After an hour and a half occupied in these proceedings, patient became so much exhausted that it was thought most prudent to postpone further examination to the following day. Respiration being performed with entire facility through the wound, a tube was not inserted. The examination, so far as they had been able to make it, ascertained the existence of a spot, of the size of a small split pea, on the inner surface

of the cricoid cartilage, posteriorly and to the left side, where the mucous membrane was wanting, and the surface was of a deep red or purplish color. The cartilage was not exposed, nor could a probe detect any track leading from it. The ventricles appeared to be in a normal condition, and the finger passed upward through the glottis could perceive nothing abnormal. The wound was left open and kept covered with compresses wet in tepid water. The pulse, which had risen to 120, subsided to 100. The succeeding twenty-four hours were passed comfortably. A viscid mucous expectoration stained with blood was expelled through the wound by coughing. On the following day at 12 o'clock the examination was resumed, and the divided edges of the larynx were stretched apart, and the interior surface carefully inspected. The spot already noticed was seen. No pus was observed on its surface or in its neighborhood.

In order to establish a tube in the trachea, it was necessary to expose and divide two additional trachea rings at the lower angle of the wound. After doing this the upper ring was detached from the lower edge of the cricoid cartilage to the extent of two lines on either side of the vertical slit, and a triangular piece clipped away with scissors from each angle, including portions of three upper rings. This converted the vertical slit in the trachea into a triangular opening, with its base upward. A silver trachea tube was then inserted and secured by tapes passed around the neck. The wound above the tube was closed in the following manner: 1st. By a single suture inserted into the muscular and aponeurotic tissues covering the thyroid cartilage on either side of the median incision. This held the opposite edges of the cartilage in exact coaptation. 2d. Four interrupted thread sutures were inserted into the edges of the integument between the tube and upper angle of the wound. 3d. The whole was supported by strips of adhesive plaster crossing from one side of the neck to the other between the sutures. Before closing the larynx the spot on its inner surface was freely touched with nitrate of silver.

The constitutional disturbance following the operation was at no time very considerable. Within one week the pulse subsided to below 80. The cough was variable, sometimes severe and in paroxysms and at other times suspended for long intervals. The expectoration ceased to be bloody after the first twenty-four hours, and during the first five or six days was opaque, viscid, and rather copious, and then gradually became transparent, frothy, and much less in quantity. During the first week the tube required to be changed twice in twenty-four hours; after that but once a day. There was no appearance of pus at any time in the expectoration, nor was there any feeling of soreness around the track of the tube. The respiration through the tube was from the first perfectly free. The wound healed above the tube by first intention, and at the end of three and a half weeks it had also healed around the lower side. Three weeks after the operation a tube perforated at its middle on the convex side was worn, and with it the patient enjoyed the use of her voice by corking the outer orifice of the tube. At first articulation was performed in a hoarse whisper, and respiration through the larynx was attended with some effort, but gradually the obstacles diminished; and during the long period of *twelve years* that she was obliged to wear the trachea tube she abated nothing of her accustomed activity in the discharge of her ordinary duties. In the summer season she often accompanied her friends on distant travelling excursions. The tube being concealed from view by the arrangement of her neck-dress, there was nothing to betray her condition to casual observers. A slight huskiness of voice, and that by no means conspicuous, was all that was noticeable.

One morning in the month of June, 1869, the patient having as usually removed the tube to cleanse it, noticed something sticking to its outer surface on the left side near the fenestrum, to which she called her father's attention, and which, on minute examination, proved to be a small fish-bone, about five-eighths of an inch in length, curved, flattened, and triangular at one end, but growing smaller and tapering at the other end.

For several weeks previous to this occurrence she had suffered from a frequent accumulation, around the inner end of the tube and the opposite surface of the trachea, of viscid tenacious secretion that would obstruct breathing and provoke violent coughing paroxysms for its expulsion.

Often she was obliged to remove these accumulations by seizing the matter with forceps inserted into the opening after first removing the tube. Sometimes they came away in a tubular shape, and were of very tough consistency. Complete relief always followed their removal.

Encouraged by the result of the laryngoscopic examinations made by Dr. F. Simrock, Dr. Buck removed the tube in January, 1870. The patient continued to be disturbed by the accumulation of viscid secretions in the trachea and the cough provoked by it for one month, when the external opening, after gradually diminishing in size, had become reduced to less than one-fourth its original dimensions, and the tracheal secretion had begun to make its way out through the larynx and mouth instead of through the tracheal opening.

Thirteen weeks having elapsed since the opening ceased to diminish in size, it was decided to perform an operation for its permanent closure. Ether having been administered, the margin of the orifice was pared away, and an incision extended a short distance above and below the opening. The skin was then dissected up on either side so as to permit the fresh-cut edges to be brought together and broad raw surfaces to be coapted, which was done by means of three pin sutures wound with cotton yarn and intermediate thread sutures.

A final inspection was made June 30th, and everything about the wound was doing well. A vertical linear depression on the surface of the trachea was all that could be felt through the superjacent skin to mark the situation of the tracheal opening. The reproduction of the excised portion of tracheal rings appeared to be complete. The parts involved in the operation were sunken in a hollow below the level of the surrounding surface. The tracheal secretion had lost its tough, viscid character, and was much diminished in quantity. Respiration had suffered no impediment since the closure of the trachea.

The question of chief interest suggested by this case relates to the whereabouts of the fish-bone during these long fourteen years of its sojourn in the larynx. The most satisfactory conclusion at which the author has been able to arrive in the retrospect of the history of the case is, that the bone, after producing violent disturbance, was suddenly dislodged while the patient was taking food, and located itself in a situation where for a few days it ceased to provoke any disturbance. At length, however, it made its way into the left ventricle, where it lay concealed, and escaped detection when the cavity of the larynx was laid open and explored. This conclusion is, perhaps, strengthened by the fact that a local soreness was felt by the patient, during the whole course of her suffering, on the left side of the larynx, and was referred by her to a spot corresponding to the

situation of the left ventricle, where outside digital pressure also produced pain. It will also be remembered that the fish-bone, when first discovered, was adhering to the surface of the trachea tube on its left side, and near its middle. It is difficult to conceive of a substance like the fish-bone imbedding itself in the soft parts lining the cartilaginous parietes of the laryngeal cavity without ulceration and suppuration. The membrane lining the ventricles, however, being lax, and more or less wrinkled, the fish-bone, so minute as it was, might easily be concealed in its folds, and escape detection. That it should have remained for so long a time is certainly very remarkable.

2d Case. *Removal of morbid growth from the cavity of the larynx by laryngo-tracheotomy. Subsequent escape of trachea tube into the right bronchus, and its removal by operation.*

John McGivney, æt. 38, native of Ireland, coachman, was admitted into St. Luke's Hospital with laryngeal trouble. The absence of all local inflammatory symptoms, together with the presence of symptoms of laryngeal obstruction, which developed themselves gradually, pointed to the existence of a growth in the interior of the larnyx as the cause of the trouble. This conclusion was confirmed by two laryngoscopic examinations made by different experts. A growth (not papilliform) was seen in the cavity of the larynx below the vocal cords. On account of the increasing dyspnœa and the severity of the suffocative exacerbations, it was decided to resort to tracheotomy without further delay. A consultation having been summoned, the operation was immediately performed, without etherization. The operation was a difficult one on account of the struggling efforts of the patient, so that in the extreme movements of respiration the cricoid cartilage would descend nearly to the level of the upper margin of the sternum.

Nothing was attempted for the removal of the intralaryngeal growth until the following day. After etherization, an incision was continued up to the os hyoides, and the thyroid cartilage exposed. The incision was also continued upward through the thyro-hyoid membrane. This permitted the two halves of the larynx to be drawn wide apart, exposing its cavity to full view. A careful examination ascertained that it occupied the right wall of the larynx and involved the ventricle and both vocal cords, underneath which it had originated, and which, together with the neighboring lining membrane, it had elevated and pushed inward so as considerably to encroach upon and narrow the laryngeal cavity. A small prolongation of the growth, somewhat pedunculated, emerged from the ventricle between the cords and protruded further into the cavity. To remove the mass entire an incision was made circumscribing its base and extending half an inch below the inferior vocal cord. The whole mass was detached from below upward. After dividing its connection above, it was found that the right arytenoid cartilage had been excised and formed a part of the mass removed. No troublesome hemorrhage followed. After the subsidence of the swelling he wore a hard rubber tube of medium size, corked at its outer end. His respiration was perfectly easy, and his voice remained very much the same as before the first operation.

The patient continued to be well up to the end of the thirtieth day after the operation, when a very extraordinary accident occurred. Having gone to bed as well as usual, the patient was waked out of sleep by violent coughing and struggling for breath. Soon, however, he became quiet and fell asleep, but was again waked up late in the night by a second attack, similar to, but less violent than the first. He now discovered that his trachea tube had disappeared, and, alarmed at the discovery, sent for the house surgeon, who on examination found, to his great surprise, that the tube had disappeared, while the plate piece which had supported the outer end of the tube, and to whichthe tape fastenings were attached, was undisturbed. On the following day the patient continued perfectly free from any disturbing symptoms, and had no consciousness of any effect from the accident. Seven days after the accident Dr. J. R. Leaming had his attention called to the case, and instituted a careful auscultatory examination of the patient's chest, and declared that the tube extended through the right bronchus into the trachea. An incision having been made, a flexible silver probe, seven inches long, fixed in a handle, slightly curved in its whole length, and bent into a small hook at its point, was passed down into the trachea with its point to the right side. When passed down to the depth of seven inches the tube was encountered, and its contact was distinctly felt and appreciated by several of those present. Having ascertained with the end of his little finger that the end of the tube presented itself obliquely to the axis of the trachea, Dr. Buck introduced a long and slender dressing forceps bent edgewise at an obtuse angle, and with it seized and brought away the tube. The forceps was exhibited to the members of the Academy.

The wound was closed as after the previous operations, and a trachea tube replaced. A copious expectoration of viscid mucus followed the operation, but without any bloody discoloration. The subsequent progress was favorable, and at the end of three or four days patient was again up and about the ward.

In fourteen days from the operation the wound had heealed perfectly above and below the tube, and all inflammatory swelling of the surface had disappeared; the patient was quite free from cough and disturbance of respiration; his voice continued very much the same as before the first operation. Desirous of returning to his home, patient was discharged wearing the tube.

On the 28th day, the trachea tube was left out entirely. Exuberant granulations which had sprung up around the orifice of the opening through which the tube passed were pared away close to the skin, and the fresh cut surface freely touched with nitrate of silver. A compress spread with cerate was applied over the opening and secured in place by narrow strips of adhesive plaster. (The patient was present and examined by the members.)

Remarks.—The state of complete quietude following this extraordinary accident, and persisting, as it did, for one week afterward, may be explained by the fact that the tubular form of the foreign body caused very little or no obstruction to the respiration. Owing to its curved shape, both ends of it rested against the wall of the passage in which it was lodged and held it at rest. This condition of quietude, however, had reached its limit. The patient, on the day of the operation, just one week after the accident, began to experience some difficulty in inspiration, and the respira ory murmur had become more indistinct over the right lung. A longer delay of the operation would no doubt have developed increasing manifestations of obstruction.

Professor S. D. Gross, in his very thorough and able Treatise on Foreign Bodies in the Air-Passages, enumerates a great variety of substances which have got into the air-passages.

Among those of a vegetable nature were beans, grains of corn, seeds of different kinds, bits of fruits, nut-shells, ears of grass and rye, cockle-burs, et

cetera. Among those of an animal nature were bits of meat, bone, shell, claws, quills, teeth, human and animal, besides a variety of other substances. Buttons, pins, needles, beads, shot, coin, nails, and other metallic substances were also on the list. Among nearly one hundred different articles of which Prof. Gross gives examples, there is no instance of a tube lodging in the air-passages, as in the case herein related. So far as he can learn, the present case is the first of its kind. It shows a very serious defect in the construction of the hard rubber tube which has come into use within a few years, and unless the defect can be corrected so as to render such an accident impossible, the further use of the rubber tube should be discouraged.

The tube itself (which was passed around) measures two inches and five-eighths in length on its convex side, and two inches on its concave; its distal end is three-eighths of an inch in diameter, and its proximal end one-half an inch, outside measurement. Its convex side is perforated at its middle by a fenestrum one-half an inch in its longitudinal diameter.

The introduction of forceps and other instruments into the trachea and bronchi through an opening in the neck, for the removal of foreign bodies, has been successfully practised in numerous instances recorded by different authors. The introduction of the finger, however, into the trachea, for the purpose of ascertaining the situation of a foreign body, is a proceeding altogether new within the knowledge of the author. The facility of this operation in the present case, and the practical advantage of it in guiding to the prompt and easy removal of the foreign body, furnished a very suggestive practical lesson to all present on the occasion. His worthy colleague, Prof. H. B. Sands, to whom belongs the priority in digital exploration of the interior of the trachea, joins him in not only sanctioning, but recommending the practice as safe, and affording a sure guide to further proceedings for the removal of the body we are in search of.

The mode of operation in this case proved to be well adapted to the employment of digital exploration. The opening in the trachea must necessarily be very free, and a vertical incision should be made of at least one inch in length, commencing at the lower edge of the cricoid cartilage and dividing the rings of the trachea. To make this opening capable of the greatest degree of dilatation, a transverse incision should also be carried across its upper extremity, between the first tracheal ring and the cricoid cartilage, to the extent of half an inch on either side. A ligature passed through the opposite edges of the wound, and including the tissues immediately in contact with the trachea, but without perforating it, with the ends tied together so as to form a loop, affords the most efficient means of stretching the edges of the opening apart. The division of the isthmus of the thyroid body necessarily involved in this operation need not be dreaded.

The author, in his numerous operations for tracheotomy, has never had any special difficulty from hemorrhage from this part, nor has he ever taken the precaution to previously ligate the isthmus on either side of the median line and cut between the ligatures. Such a precaution might easily be taken and would be a complete security against hemorrhage. After previous digital exploration the author's forceps are best adapted to seize a foreign body in the trachea below or in the larynx above.

The speaker, in concluding, remarked that he had been fortunate in having access to a prize essay by Bertholle, written in 1865, in which 130 cases of foreign bodies were noted, including those mentioned by Prof. Gross.

In this essay there is no instance of a tube lodging in the trachea and bronchi. We learn from experience that operations show the best chances of success, and according to Bertholle nearly half of the cases not operated on died; expulsion followed by recovery and not operated, a little more than 1 in 2 recovered; of 45 operated, 33 recovered and 12 died—nearly 3 out of 4. Aaronsohn reached a similar result: of 68 operated, 50 recovered and 18 died—or 5 out of 7. The importance of auscultation in cases of foreign bodies is clearly exhibited in this instance.

Before sitting down, the larynx, trachea, and bronchi from the cadaver were presented, to show how the tube was lodged.

Prof. Alonzo Clark referred to a case occurring in the practice of Dr. Lindsay, of this city, where a lady, æt. 45 or 50, while holding a silver ten-cent piece in the mouth, suddenly lost it. Paroxysms of coughing followed. After it had remained for two years, Dr. L. wished the speaker to find by auscultation where it was located. He was informed that it was in the right bronchus, where it remained for three or four years. Eighteen months ago Dr. Lindsay brought this silver piece to him, which was as black as charcoal, and in three or four pieces. It had turned into the sulphuret of silver.

The subjoined case, originally under the observation of Prof. Jas. R. Wood, was alluded to: A gentleman came to him with cough of three or four years' standing, occasioned by the presence of a piece of chestnut-shell in the right bronchus. One year from that time he had pneumonia. Within six years from the attack of pneumonia a piece of the shell was coughed up, which had undergone a chemical change. The patient was told that he would wear out in one year. Dr. Clark also mentioned the case of a boy, who, in haying-time, took a head of timothy into his mouth, which was carried into the breathing-tube. His friends said that he had not swallowed it, but it was found one month after imbedded in the lungs.

Prof. Frank H. Hamilton referred to one of his cases which was reported by Prof. Gross, where a lad had swallowed a tin whistle. It was found in the right bronchus, but the patient was not operated upon. In two weeks from the time of swallowing it was coughed up. This author believes that the number of cases of foreign bodies expectorated are not as often recorded as the successful operations for their removal; consequently, we cannot rely altogether upon the published statistics. His success in the removal of foreign bodies without an operation has been remarkable. He sees no advantage in the use of a hard rubber tube after laryngo-tracheotomy.

Dr. Alfred Underhill had, six or seven years since, a case of phthisis occurring in a female who had swallowed six years previously a copper umbrella-tip, which was detected at the point where it lodged. While in a paroxysm of coughing the tip came up. The expectorations previously to that time were of a copperish-yellow hue, but afterwards the color of the discharge ceased.

He also referred to two other cases of foreign bodies which were relieved by the administration of emetics. In one case it was a pin, in the other a bean, which caused the trouble.

Dr. Buck stated that Dr. Jas. R. Wood once related a case of a child which was brought to his office in East Broadway by the mother, who said it had swallowed a thimble. It was quickly removed with the finger, which made quite a sensation among the numerous spectators.

Prof. E. R. Peaslee asserted that, in most cases, the

body was in the right bronchus, and the presumption was that it should be so, as the right side was the largest. In regard to detecting the precise point of the body, he coincides with Dr. Leaming. He narrated a case where a large sponge was said to have passed down the larynx, and he could hardly believe that so large a body could be swallowed, but on auscultation a surgical operation was attempted and the sponge brought away. It measured one inch in length, and one and a quarter inches in thickness. The patient died forty years afterwards. In this case the bleeding following the operation did not occasion a cough at all, but a cough had to be excited so that the blood could be brought away. The air-passages will bear a good deal of manipulation after operation.

Dr. A. J. Chadsey once relieved a patient who had swallowed a fish-bone, by promptly administering an emetic, with the head downward. Another case was reported by Dr. Chadsey, which came under the observation of Dr. Kittredge, of Mass., several years since, where a man had swallowed a bean, and the wife had recourse to the following novel method of relieving her husband. Some balls of butter were prepared, and the patient asking her what they were for, the reply was, that she should fire them at his posterior. This remark caused him to laugh immoderately, which brought up the foreign body.

On motion of Dr. Elisha Harris, Drs. H. D. Bulkley and E. H. Janes were added to the Committee on Vaccination, as they had had a good deal of experience on the subject.

On motion, the Academy adjourned to the third Thursday in September.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 22, 1870.

Dr. Joseph C. Hutchison, President, in the Chair.

The Committee on Microscopy reported the supposed epithelial cancer of the lip in a young man to be fibroplastic.

NECROSIS OF SUP. MAXILLARY.

Dr. Knapp presented a portion of the necrosed body of a superior maxillary bone removed by operation from a male patient, aged forty. The interest of the case consisted in the fact that the whole orbital plate of the superior maxilla was gone, and in its place the fistulous tract had so drawn itself under the eyeball as to form a complete cushion for it.

Dr. Hart exhibited an osseous tumor of the left cornu of the thyroid cartilage removed from the body of a Frenchman aged forty. The disease in its progress had completely dissected out the carotid artery. The specimen was by request referred to the Committee on Microscopy.

MALIGNANT DISEASE OF ŒSOPHAGUS.

Dr. Loomis presented an œsophagus taken from an Irish widow fifty years of age, who was admitted into Bellevue about the first of June. She stated at the time of her admission that she had always been a hard-working, temperate woman, and had been perfectly well until about six months before, when she began first to suffer from pain in her chest. She located the pain at a spot corresponding to the junction of ensiform cartilage and sternum. When first felt it seemed deep-seated, paroxysmal in character, and worse after eating. Very soon, in connection with pain, she noticed a difficulty in swallowing, the act being accompanied by a choking sensation. The difficulty did not seem to be in the food passing the pharynx, but it seemed to be lower down. She also noticed that within a very short time after the pain commenced she was unable to swallow solid food, or after she had swallowed it, it was very soon returned unchanged. She confined herself accordingly to fluids, and began as a consequence to lose flesh and strength very rapidly, so that at the time of her entrance she was unable to get out of bed or stand without assistance. Her skin had a pale, dingy hue, her countenance was anxious in its expression, and she had a much older appearance than her years indicated. She felt best when sitting up. When she lay down she suffered from pain, which was always aggravated when she attempted to swallow. She described this sensation as a soreness more than a lancinating pain. She would not attempt to swallow solid food; but when she would take milk, after a minute it would regurgitate, and although the act was continued during the regurgitation, she still seemed to get very little into her stomach. An œsophageal probang was introduced into her œsophagus, and it met with an obstruction at the lower bend of the tube; but, after considerable manipulation, was at last introduced into the stomach. She said that she swallowed better after the operation, and the operation was consequently repeated several times. About a week after her admission she vomited a considerable quantity of fluid. On the 19th of June she sank and died from exhaustion, the result of want of food.

On post-mortem examination the œsophagus was the organ principally diseased. It presented very nearly a normal appearance down to its lower third, where there was a growth springing out as it were upon the inner surface and surrounding the tube for about two inches. This new growth had considerable consistency at some points; at others it was very much softened. Close examination seemed to show that it sprang from the deep submucous cellular tissue, and that at its lower portion there was a small opening which communicated on one hand with the base of the lung, a portion of which latter had undergone induration; on the other hand it opened into the left bronchus. This growth commenced opposite the bifurcation of the bronchi. It did not involve the stomach, nor were there any other cancerous deposits in any particular organ of the body. There was some œdema of the lungs, and the tubules of the kidneys were granular.

The question was whether this woman's death was hastened by the probang. Another point:—This was a primary development, as almost all cancers of the œsophagus are. Again, this woman suffered very little from anything save the difficulty of getting food into her stomach.

CARDIAC DISEASE, ETC.

Dr. Jacobi exhibited a specimen removed from the body of a gentleman who died at the age of thirty-six years. About three and a half years ago he had been taken with a very severe endo-carditis, in the course of an attack of acute rheumatism. He suffered from the beginning with a very high fever, which, continuing for a long time, gave the impression of being the concurrent fever of miliary tuberculosis. Still, at a later period no symptoms of tuberculosis or other lasting pulmonary disease could be found. Dr. J. saw him about six months after his first attack, and had occasion to make the diagnosis of stenosis of the aortic orifice and incompetency of the mitral valve. He afterwards attended to his business, had in the mean time a little œdema of the feet, would be down now and then with severe pulmonary catarrh, and a few times with what had been taken to be attacks of localized pneu-

monia. A quarter of a year before his death his symptoms grew worse, and he died finally with the usual symptoms of cardiac disease, viz., œdema, dyspnœa, now and then intercurrent pulmonary œdema, and occasionally with localized pneumonia. Not a single one of the latter appeared to extend over more than one lobe at a time, and in every one resolution of the new-formed infiltration took place.

At the autopsy a large number of warty excrescences were spread over the endocardium. The semilunar valves were shrunken by the deposit. The mitral valve was in a similar condition. The right ventricle was thickened and dilated. The spleen was very much enlarged and showed infiltrations from the size of a pea to that of a hazelnut. All of them were of pyramidal shape, base outwards. There were some spots in which cheesy degeneration of these infiltrations had taken place, with probable exudative inflammation in the neighborhood. There were two large abscesses, of more than walnut size.

ECHINOCOCCUS OF LIVER—REMOVAL OF CYST BY OPERATION, ETC., ETC.

Dr. Jacobi also presented a specimen of more than usual interest, and gave the following history of the case to which it belonged:—

The specimen was removed from the body of an unmarried woman twenty-nine years of age, who died at the Mount Sinai Hospital, on the 15th of June. Her history for the past few years is incomplete; I have only a few notes of the same from the house physician. She was admitted in the summer of 1868, with the diagnosis of chronic gastric catarrh. At that time she suffered a great deal from indigestion; there was a good deal of bloating, with an absence of appetite. It was found that the right side of the body at the height of the seventh or eighth rib was two inches larger than the left. She remained in the hospital twenty days and was then discharged as cured; that is to say, she had regained her appetite, etc., although no mention is made of any change in the shape of her body. She remained away until December, 1868. This time she is marked down with pneumonia. She had been sick three or four days before her admission, and remained in the institution about nine days. She left with a little cough, but to all appearances was well. No mention is made of any differences of measurement of the two sides of her thorax. Was re-admitted October, 1869, with an exudation in the right pleural sac. She had complained for about two weeks of a good deal of pain in the right side. On examination there was dulness from the scapula downwards to the liver, or what was considered to be the liver. No respiratory sound was heard. She had the proper treatment for pleurisy, and appeared to be improved in the first days of November. She then had slight fever; also about the beginning of November she menstruated; again after menstruation, having more pain, a blister to the right side was applied. She took quinine and improved. In December, although she felt very much better, she still did not feel well. The iod. of potassium which she had taken before was omitted, but she was permitted to remain in the hospital.

It is noted that on December 30th, respiratory murmurs returned over part of the affected side. During January, February, and March, she was allowed to remain, and as usual with such chronic cases, no great attention was paid her.

My service commenced in April. On the 11th of that month I found the circumference of her chest to be thirty-four and a half inches, there being a difference of five and a half inches in favor of the right side. Inclined to think that the enlargement of the liver was due to leucocythæmia, I ordered her a few days afterwards to come to my office for the purpose of having her blood examined. She came on the sixteenth of April. I examined her blood, and counted about twenty white corpuscles to three hundred and fifty red ones, evidently a large increase over the normal proportion, but at the same time not enough to justify the diagnosis of leucocythæmia to such a degree as would coincide with the immense size of the liver. It should be stated that this examination was made two or three hours after her dinner, which in a measure accounted for the disproportion of lymph corpuscles. I examined her again five or six days afterwards, and at that time did not find more than five or six white corpuscles to the three hundred and fifty red. I then gave up the idea of leucocythæmia, and on the 29th of April I plunged in an exploring needle in order to satisfy myself as to the nature of the disease. A few days previously I thought I felt fluctuation a little to the right of the median line, and about an inch and a half below the margin of the ribs. This caused me to make up my mind to use the needle, and I was supported in my decision by the other members of the staff. At the time of the operation it appeared that there was not only one elastic spot in the situation described, but another one a little to the right of it. These did not seem to communicate. I brought away a few drops of a thin clear liquid, which was subjected to a microscopical examination without, however, the desired result of revealing what I was looking for, the hooks of the echinococcus. But as it contained a good deal of chloride of sodium, and as it not unfrequently happens that no hooks can be found, I made up my mind that I had to deal after all with an hydatid cyst, which, from the small escape of liquid contents, forced me to the conclusion that it was of a multilocular character.

After the exploration had been made she was left quiet for some time. A little peritonitis set in, and for the present I could not think of doing anything more. I hoped that there would be sufficient adhesion between the abdominal wall and the sac to finally justify the opening of the latter. The peritonitis disappeared so soon that I could not feel sure of the adhesion. After her general condition had improved, I determined to apply the Vienna paste, for the purpose of lighting up the desired amount of inflammation. Meanwhile I had measured the liver by percussion, and found anteriorly dulness above the fourth rib anteriorly and posteriorly; that the same tumor could be felt in the neighborhood of the umbilicus, in the right hypochondrium to the height of the umbilicus, and in the left a little above—thus the surface of the liver measuring from eight to eight and a half inches in a longitudinal direction. The Vienna paste was applied on the 21st of May. In order to have a sufficiently large opening into the sac, I applied it just over the region where I found the greatest amount of elasticity, over a space four and a half inches in width. A second application of the caustic was made on the 22d, a third on the 24th, after which peritonitis set in. There was a good deal of fever; the pulse went up, but still I went on. The peritonitis was just what I wanted. On the 27th there was a fourth application, on the 30th a fifth, and the 31st a sixth. On the 1st of June I found, after I had removed shreds of necrotic tissue, that I was outside of a thin layer that might be the thickened sac-wall itself. Still I did not feel justified in introducing the knife, and applied the caustic once more. On the afternoon of that day the sac burst, discharging an immense quantity of water, shreds of membrane, etc. The amount of liquid that was poured out was estimated to be at least half a

pail full—at all events, it was sufficient to inundate the woman, bed, and a large portion of the floor. On the 2d of June I found the opening an inch in size, and large enough to admit the finger. Inside the sac, the walls of which I could follow up for a short distance, I found a number of membranes that looked to me like floating hydatid. I dilated the opening to two and a half inches by means of the knife, and removed that day a number of shreds and membranes. I repeated the latter almost every day. Some particles would float in the liquid that I injected, or rather poured in, and were easily removed.

The walls of the sac were very stiff, so that they would not collapse, and I could from the first day inject a pint of liquid and over. The first injection consisted of from three to four grains of carbolic acid to the ounce of water. Sixteen to eighteen ounces were injected at a time. After a while I thought that with smaller injections I might do better and facilitate the contraction of the sac; thus a few ounces of liquid containing seven grains to the ounce were poured in. The first days she felt tolerably well, with the exception of a very severe pain in the region of the kidneys and along the line of the vertebral column. This I attributed to the stretching of the adhesions. A number of days after the sac had been opened she was taken with moderate fever, her temperature never, however, got beyond 102° until four or five days before death, when it arose to 103°.

On the 8th of June, just a week after the final operation, or rather after the bursting of the sac, some shreds were again removed which were floating in the liquid. On the 9th I succeeded in removing through the external opening this large sac entire. It consists of a large number of layers that can easily be separated from each other, and its walls are one-sixteenth of an inch thick. On its internal surface are small excrescences, which prove to be small echinococci, or rather scolices.

I present to you here all that is left of that immense liver, showing that the echinococcus sac has taken the natural place of the right lobe of the liver. But a very small portion of the right lobe is left intact. But there remains the immensely enlarged left lobe, enlarged evidently in consequence of physiological congestion, and the necessity of vicarious function resulting in new-formed liver substance.

At the autopsy adhesions were found everywhere, to the diaphragm, intestines, and kidneys, and in such manner as to prevent the contraction of the sac. The capacity after the rupture was a little more than a pint. The sac was removed by a blunt forceps. I proceeded in the way I did because I felt that I should have a better chance in saving her by the creation of adhesions than by puncturing at once. I have consulted Murchison, who collects a number of cases (none of the sacs as large as this) in which they have been punctured simply, and he has a number of recoveries; still I don't believe that it would be safe to puncture simply and then leave the case to itself. My operation is advised by Recamier, of Paris, I think. Dr. Simon introduces wire through the tumors, fastens them on the outside, and then waits for peritonitis, and after adhesion takes place, opens the sac with a knife. An operation similar to that was performed by the late Dr. Ed. Weber, of this city. It is reported that he made an incision horizontally down upon the liver, and waited eighteen days, then opened the sac (which contained two quarts), and injected iodine, and after the contraction had left fistulous openings, these in their turn were closed by nitrate of silver. This case is reported as having got well.

The Society then went into executive session.

Correspondence.

CHLORAL POISONING.

To the Editor of the Medical Record.

Sir—About 10.30 P.M., July 2, 1870, I was requested to see Mr. B., æt. 46, born in England. For years he has been addicted to drink. In the last two years he has acquired also a habit of using opium, which indulgence he had carried to such excess that tinct. opii ʒ ij. or McMunn's elixir ʒ iij. would fail to produce sleep. Bromide of potassium also failed to produce the desired effect. Three weeks prior to my call he had begun the use of "chloral" in doses of grs. xv. to xx., which made him sleep. He increased the dose (as he had heretofore done with other narcotics and sedatives) to ʒ j. On this occasion the ʒ ij. which had been ordered for him at 6 P.M. not having quieted him before the renewal of that dose at 10 P.M., he impatiently seized the bottle and drank ʒ iij., making a total of chloral hydrat. ʒ v. in four hours. Five minutes after he was observed to grow quiet, his eyelids drooping. After ten minutes his respiration became slow, labored, and stertorous. Five minutes later he fell from his chair. A pipe being in his mouth was removed with much difficulty, his teeth being firmly closed. Forty minutes after taking the last chloral I saw him. Respiration was then 48, shallow, and loudly stertorous. Pulse rapid, weak, and wavy; pupils contracted to size of pin's head, but extremities warm and oxygenation good, although he was completely and profoundly anæsthetized.

I applied mustard to præcordia and administered brandy and water. Deglutition was difficult, the act not beginning until he strangled and coughed. About 11 P.M. Dr. Gurdon Buck saw him and suggested an application of mustard to back of neck. Shortly after taking the brandy his pulse became more regular and could be counted, being 120. For half an hour no material change appeared in his condition. Before 12 o'clock respiration became deeper and less frequent. At 12.30 pupils dilated somewhat, and the loose flabby faucial muscles appeared slightly tense, indicated by a less degree of stertor. At 1 o'clock flexed and extended his right leg. In a few moments he vomited, immediately after which greater dilatation of pupils was observed, afterwards contracting again. He soon experienced very slight clonic spasms in his limbs, which were of short duration and at irregular intervals, lasting about twenty minutes. Administered brandy ʒ iss and water, until deglutition improved, then commenced with beef-tea and brandy. At 1.30 he opened his eyes wide for a moment, after which he sighed when aroused by the act of deglutition. At 2 A.M. retired, to be called if any change occurred. At 5 A.M. was called, found patient quite pale, pulse weak, 108, respiration 26. Sensibility to touch of conjunctiva. He turned upon his right side and remained until 7½ o'clock, when he looked much better, opened his eyes and talked, but again fell asleep. Continued beef-tea and brandy. Between 8 and 9 o'clock he walked upstairs with some assistance. At 12 M. he was comfortable, talking rationally, but still inclined to sleep. At 8 P.M. still quiet, eating and sleeping.

R. J. McKay, M.D.

47 West 26th Street, July 10, 1870.

THE MASSACHUSETTS MEDICAL SOCIETY AND THE QUACKS.

To the Editor of the Medical Record.

Sir:—That the Massachusetts Medical Society's

"statutes provide for the admission of irregulars into its body," as intimated in a recent number of the RECORD, is a mistake. On the contrary, one of its by-laws explicitly says: "No person shall hereafter be admitted a member of the society who professes to cure diseases by spiritualism, homœopathy, or Thompsonianism."

There are, however, more or less homœopathists in the society who, notwithstanding the permission allowed them to retire, persistently maintain their connection in consequence of the *éclat* which the position furnishes them. Some have crept in clandestinely, more have become irregular after having joined the society; and it has generally been considered by us best to let them quietly alone—*to ignore them as practitioners and as members*, rather than give them the benefit of the notoriety and the sympathy in the community which would be consequent on a formal trial and expulsion. We use special care to keep out new interlopers of exceptionable cast, and while we deal out to those already in, the fullest measure of neglect and contempt, we wait patiently for them to die off, as the safest and easiest way to be rid of them.

A MEMBER OF MASS. MED. SOC.

July 28, 1870.

Obituary.

PROFESSOR ALBRECHT VON GRAEFE.

ONE of the greatest men in our profession is no more. A cable despatch tells us that the Professor of Ophthalmology in Berlin, *Albrecht von Graefe*, is dead. This sad event is not wholly unexpected, since for years the numerous friends of this great man have been very solicitous in regard to the state of his health, and the vacations demanded by his exhausted frame have been long and at short intervals. We are not in the possession of exact data as to von Graefe's age, but he was probably about forty-five years old. His father was a distinguished surgeon and ophthalmologist, and also, we believe, a Professor in the Berlin University. After von Graefe the son had finished his medical studies, he determined to devote himself to the study and practice of ophthalmology, and for that purpose studied in Paris and Vienna. The latter-named place was then pre-eminently the centre of ophthalmic science. It had received more encouragement at this university, where the professor of this department enjoyed the same rank with the teachers of Anatomy, Practice of Medicine, etc., than in any other school. Graefe was here a pupil of *von Jaeger*, the great ophthalmoscopist. Having spent some years in special study, he returned to Berlin, where he established with his own means an hospital for the treatment of diseases of the eye. In this hospital the greatest triumphs of ophthalmology have been achieved. Here von Graefe first performed the operation of iridectomy for glaucoma; here *Liebreich* made those representations of the ophthalmoscopic image of the *fundus oculi*, which have contributed much to our knowledge of the diseases of the interior of the eye; here *Schweigger* made those wonderful sections of the cornea, choroid, and retina; and more recently, in this hospital, von Graefe, who had already extracted more than 6,000 senile cataracts, introduced a new method of operation—the peripheric linear—which has well-nigh taken the place of all other operations for hard cataract. In fact this *Augen-Klinik* became the centre of modern ophthalmology, to which all other schools, however celebrated, were but the radii.

Graefe, in conjunction with Professor Arlt, of Vienna, and Professor Donders, of Utrecht, established the *Archiv für Ophthalmologie*, a semi-annual journal, which has reached its fifteenth volume, and one which is always mentioned first in any enumeration of ophthalmic literature. Probably one-third of all which has appeared in this journal was from the pen of Graefe himself, and he who possesses it has a complete library of ophthalmology.

Graefe's labors as a teacher, where he instructed large classes of graduates in medicine from his own country, from Russia, France, Spain, America, in fact from all parts of the world, were very great. Nearly every day during the winter sessions he lectured for two hours on illustrative cases, besides performing numerous operations in the presence of sections of the class; for he recognized the fact that it was possible for but few to see an eye operation at any one time, and he admitted only that number to the bedside. At his clinic he was always gentle and courteous to the poor, who came to him in crowds; and when in some hopeless case his art could avail nothing, he would often slip a gold piece into the hand of the poor unfortunate, as if resolved to do something to alleviate the sad condition.

His private patients were also treated in his large hospital, where he had rooms fitted up in accordance with the habits of life. He was also an attending surgeon to the Charity Hospital, where he had some two or three wards.

Although Berlin is a city of some 700,000 people, and there were men in the profession able in many respects to compete with him, he had no competitor in the true sense of the word. Any chance street-passer, if asked who was the greatest oculist in Berlin, would have unhesitatingly answered *Graefe*. He had numerous assistants in his clinic and hospital—usually no less than five—but none of them were ever in any sense his rivals. If *Graefe* had a weakness, it was that he made his school so much a part of himself, that now that he is gone it will die also.

Graefe established an annual conference of ophthalmologists at Heidelberg, which has contributed much, in the papers read, and the discussions incident to them, to the advancement of a science which is now far ahead of many departments of the general field.

From his clinic has gone out the most of the teachers of ophthalmology in the known world; to sketch his life is to give the history of modern ophthalmology.

It is hard to speak of him without exaggeration; but the thousands who were under his care, his students scattered over the whole earth, will sustain the statement that in losing Graefe we have lost to medical science what Homer and Shakspeare were to poetry, Aristotle and Newton to science, Alexander and Napoleon to war; but, like them, he has left an immortal memory.

In person he was tall, with a bright blue eye; his hair was dark, of late sprinkled with gray. He was a nervous lecturer, speaking rapidly, but clothing his thoughts in classical German, and with such vehemence as to occasionally gasp for breath. As an operator his large experience, probably greater than that of any living man, made him excel; but he laid greater stress on careful observation after an operation, than any surgeon whom we have ever followed. He watched his cases with an assiduity and skill which often brought a good result from a seemingly hopeless one.

We have no advices of the disease of which Graefe died, but it was probably an affection of the chest, from which he frequently suffered.

Medical Items and News.

Prof. Lister has been appointed Surgeon in Ordinary to the Queen in Scotland.

Sir W. Fergusson has been elected President of the Royal College of Surgeons, London.

Surgeons for the Prussian Army.— American surgeons with a knowledge of German are invited to join the Prussian Army.

Glyceratus—A Substitute for Simple Syrup.—H. Treverton Bond, of Wheeling, West Va. (*Am. Journal of Pharmacy*), suggests the following preparation, which he has christened "Glyceratus," as an article that in many prescriptions can be used with advantage in place of simple syrup: Take of glycerin, one pint; water, two pints; mix them.

The objections to simple syrup are too well known to need mention, while the great solvent power of glycerine renders it far superior in many instances. This preparation undergoes no change, and can be readily made.

Balata.—For some years past an article has been met with in commerce under the name of balata, which has properties intermediate between caoutchouc and gutta-percha, and is used for similar purposes.

Balata is prepared from the milky juice of the bully tree, *Sapota Muelleri Sapotaceæ*, which is indigenous to Guiana, the product being exported to Europe, mainly from Berbice. It contains 88·49 carbon and 11·37 hydrogen. In the dried milky juice of the bully tree, Sperlich found 81·31 carbon and 10·17 hydrogen; the balance is ascribed to oxygen.—*Am. Journal of Pharmacy.*

A Case of Poisoning from Swallowing Percussion-caps.—Dr. J. C. Whitehill, St. Louis, Mo., editor of the *Medical Archives*, reports a unique case of poisoning in a child of sixteen months, by swallowing *thirty-two* percussion-caps, which was partially relieved by administering an emetic of ipecacuanha and sulphate of zinc. The oil of sweet almonds was given freely to allay irritation, which it seemed promptly to do, and to protect the gastric walls, followed with a large dose of castor oil. In the course of a few hours the oil acted freely, and during the following day the child voided, per anum, twenty-three caps, making, with the nine previously thrown up, thirty-two in all, that he had swallowed. In this case, the effect of the oil of sweet almonds was prompt and satisfactory.

A Case of Dislocation of the Humerus from Sneezing.—A novel case of this character is published by O. H. Garritson, M.D., Macomb, Ill. (the *Medical Archives*). The patient, æt. 42, a carpenter by trade, while combing his hair, preparing for breakfast, suddenly sneezed, and dislocated the head of the humerus into the axilla. This was easily reduced, and the after-treatment consisted simply in supporting the arm in a sling for a few days. The rationale of the dislocation is not certainly known by Dr. G., but the reader may judge for himself. The patient says he was combing his hair with the right hand, and was holding his left arm nearly on a line with the coracoid process of the scapula. In the act of sneezing we naturally throw the head forward, and the arm at the time being held in the position he had his, the muscles being relaxed, save sufficient to retain the position, through the involuntary, sudden contraction of the deltoid, brachialis anticus, and biceps muscles, the elbow will raise, and the head of the humerus be correspondingly or proportionately depressed. This, he believes, must have been the cause of the dislocation.

Childless Women in New York State.—According to Dr. S las Loomis, Washington, D. C. (*National Med. Journal*), twenty-four per cent. of the women of this State are childless, and nearly twenty per cent. are incompetent after bearing one child.

Abernethy and a Medical Student.—The following scene between Abernethy and a medical student is worth noting, showing the audacity of the latter:—

"What would you do," bluntly inquired the surgeon, "if a man was brought to you with a broken leg?"

"Set it, sir," was the reply.

"Good—very good—you're a very pleasant, witty young man; and doubtless you can tell me what muscles of my body I should set in motion if I kicked you, as you deserve to be kicked, for your impertinence?"

"You would set in motion," responded the youth, with perfect coolness, "the flexors and extensors of my right arm; for I should immediately knock you down."

A Remedy for the Waste of Vitality of American Women.—The following indications to remedy the reckless waste of vitality in the female are laid down by Silas L. Loomis, M.D., Prof. of Chemistry in the Howard University:—

A child should not enter a school-room before 8 years of age for the purpose of study.

From 8 to 12 no studies involving close reasoning should be allowed. The hands, feet, eyes, ears, and body generally should have had careful instruction.

From 12 to 14, health should be the first object. All else subservient. Health at all times should be a prime object, but at this period more than ordinary attention is demanded.

At 15, education should begin in earnest, to be completed *generally* at twenty, or *professionally* at twenty-five.—*National Med. Journal.*

Oxygen Gas Introduced in the Paris Streets.—The new Préfect of the Seine has authorized the Tessie du Motay Company to lay their underground communications in the city of Paris, for illuminating with oxygen gas.

Meat Preserved Nineteen Years.—Dr. Stein (*Jour. of Applied Chemistry*) while lecturing recently at Dresden on the preservation of meat and food, produced a tin cannister of good size, containing butcher's meat preserved by Appert's method, and prepared by himself in 1851. On opening the cannister, which had been filled nineteen years previously, the meat was found to be as fresh and full of flavor as when it was first placed in the cannister.

A Donation to the Hospital at Hartford, Conn.—The late Chester Adams, of Hartford, Conn., bequeathed the sum of $40,000 to the Hartford Hospital.

Intoxicating Liquors Drank in the United States.—The quantity of fermented and distilled liquors used in the United States in one year, would fill a canal four feet deep, fourteen feet wide, and 120 miles in length.

The Origin of Rhinoscopy.—Bozzini, in his work *Der Lichtleiter*, published at Weimar, in 1807, was the first to describe a "certain simple apparatus" for the examination of the "internal cavities and spaces in the living animal body," including therein the parts situated "behind the hanging palate."

Prof. James S. Cabell.—This distinguished medical professor in the University of Virginia, is the resident physician at the Hot Springs in Bath County, Virginia.

Blisters Abandoned.—Dr. Peter, of Paris, has abandoned the use of blisters for counter-irritation, and uses the tincture of iodine in preference.

Bread and Milk Diet in the Carcinomatous Diathesis.—Prof. Paul F. Eve, M.D., Nashville, Tenn., has never known a case of cancer not benefited by this diet, first suggested by Dr. Nathan Smith, of New Haven, Ct., and afterwards demonstrated by Dr. Twitchell, of Keene, N. H., in his own person, when seventy years old.

Vomiting of Pregnancy.—Carl Both, M.D., of Boston, Mass. (*Jour. of the Gynæcological Society*), knows of nothing to compare with raw meat in vomiting of pregnancy, the meat being chopped fine and slightly salted. It should be given in very small doses at first, and then gradually increased. For drink he prescribes Seltzer water, or the Star water of Saratoga.

Digitalis in Uterine Hemorrhage.—Dr. W. Howship Dickinson, one of the physicians to St. George's Hospital, London, first directed the attention of the profession to digitalis in connection with uterine hæmorrhage, in 1854. His statements were fully confirmed by other observers, including Barclay, Trousseau, and Decaisne.

Renal Origin of Dropsy.—In 1761 Morgagni pointed out the renal origin of dropsy, and gave the first authentic intimation of convulsions as a sequence of kidney disease. A few years later, 1770, we have the first undoubted discovery of albumen in the urine, by Cotumnius. In 1797, Cruikshank showed the relation between coagulable urine and dropsy.

The Kidney.—The tubes of the cortical portion of each kidney have been estimated at 2,000,000 in number, thus furnishing, according to Vierodt, a secreting surface of 44 square feet.

A Heavy Liver.—Murchison, in his "Diseases of the Liver," has recorded a waxy liver weighing 180 ounces.

The Amyloid Deposit in the Spleen.—Hodgkin, in 1832, without expressing any opinion as to its nature, was the first to recognize the amyloid deposit in the spleen, and especially that form known as sago-spleen.

The Waxy Change in the Kidney.—The discovery that the transparent or waxy change of this organ begins in the minute arteries and capillaries, was made by Dr. Kirk in 1853.

Dr. Dieulafoy's "Aspirateur Sousautane."—Under this name an instrument has been suggested, by means of which effusions into synovial or serous membranes, collections of pus or blood, and even hydatid sacs, may be safely evacuated It consists of an instrument resembling a subcutaneous injection or syringe, with a terminal and a lateral tube, fitted with stop-cocks, to which a capillary trocar can be fitted, so that after withdrawal of the morbid liquid an injection may be practised without removing either the trocar or the pump.—*Med. Times and Gazette.*

Hydrated Sesquioxide of Chromium.—C. J. Rademaker, M.D. (*Am. Journal of Pharmacy*), states this preparation has been used with great success in Louisville, Ky., by Dr. Wilson and others, in the treatment of cholera infantum.

The Motion of the Wings of Birds.—The remarkable discovery made by Dr. Pettigrew in 1867, that the wings of all animals are twisted upon themselves, and that they twist and untwist during their action, has quite recently been confirmed by Professor Marey, of the College of France. This gentleman has experimentally demonstrated the character of the air-path of the vibrating wing, and has shown, as Dr Pettigrew had already proved, that the wing during its oscillations describes a figure of 8 track, which, in horizontal motion, becomes converted into a wave-track. Dr. Pettigrew's discovery and Professor Marey's demonstration are of great interest to aëronauts.—*British Medical.*

The Mode of Termination of Motor-Nerves in Organic Muscle.—M. Hénocque has been making a series of investigations on this subject, the result of which he communicates to M. Brown Séquard's *Archives de Physiologie* for May, and has arrived at the following conclusions:—1. The distribution of the nerves in smooth muscle is not only identical in man and other vertebrate animals in which it has been observed, but is essentially similar in all the organs containing smooth muscle. 2. Before terminating in the smooth muscles, the nerves form three distinct plexuses or networks—(*a*) a chief or fundamental plexus, containing numerous ganglia, and situated *outside* the smooth muscle; (*b*) an intermediate plexus; and (*c*) an intramuscular plexus, situated *within* the fasciculi of smooth fibres. 3. The terminal fibrils are everywhere identical; they divide and subdivide dichotomously, or anastomose, and terminate by a slight swelling or knob, or in a punctiform manner. The terminal swelling appears to occupy different parts of the smooth muscular fibre, but most frequently to be in the neighborhood of the nucleus, or at the surface of the fibres, or, lastly, between them. The methods of investigation adopted by M. Hénocque have been very numerous, including the maceration of the preparations, obtained in as fresh a condition as possible, in aqueous humor, artificial serum, pyroligneous acid, chromic acid, chloride of gold and potassium, especially the latter, in a strength of 1-200th.

Purulent Infection—Cure by Sulphate of Quinia.—A man, aged twenty-six, was admitted to hospital for a cold abscess of the thigh, having its point of departure in the femur. As the abscess threatened to open spontaneously, M. Ripoll, says the *Gazette Médicale de Paris*, made a slight incision, which gave exit to pus. Seven days afterwards the patient had two violent rigors, followed by all the symptoms of blood-poisoning. An emetic of ipecacuanha was administered, and, subsequently, tonics and seven-and-half grains of sulphate of quinia. During the following days the quinine and other tonics were continued, and that for more than three weeks. Improvement was slow, but progressive, and M. Ripoll, with reason, attributes it to the quinine and tonics.

Liniment in Fissure of the Anus.—Dissolve one part of tannic acid in sixteen parts of glycerine. A piece of lint dipped in this solution should be introduced night and morning into the rectum. The bowels should be kept open. By means of this preparation M. Van Holsbek, its originator, has succeeded in healing anal fissures which have resisted the division of the sphincter.—*L'Union Médicale.*

Lead Poisoning.—M. Didierjean, of Paris, has found an efficacious preservative of saturnine diseases. He has experimented within the last two years with the workmen employed in the lead works. This preservative is milk, of which every workman brings with him

to the manufactory 1,000 grammes every day, and for eighteen months no workman has been ill with lead poisoning.

MORPHIA COLLODION.—Mix together one part of hydrochlorate of morphia and thirty parts of flexible collodion. The collodion is applied by means of a camel's-hair brush to the seat of neuralgic pains. Should these occur periodically, larger or smaller doses of the sulphate or the valerianate of quinine are to be given besides.—*L'Union Médicale.*

INFLUENCE OF VACCINATION ON SMALL-POX.—M. Farivel presented to the Academy of Medicine of Paris, at its last sitting, the following conclusive statistics:—From the 18th of February to the 31st of May 275 cases were treated in the Hôtel Dieu. Of these 275, forty died—1 in 7, or 14·55 per cent.—185 were cured, 50 remained under treatment. Of the 275, 28 had never been vaccinated, of whom 21 died—75 per cent. 247 had been vaccinated in childhood, of whom 19 died—7·69 per cent. Of the 247 who had been vaccinated, 12 had been re-vaccinated within the last three years—all were cured. Three were re-vaccinated (two of them successfully) during the period of incubation—all were cured. Thus not one of the re-vaccinated cases died, and it is remarkable that the three cases re-vaccinated during incubation were the only cases which took the variola out of 1,017 vaccinations performed at the Hôtel Dieu since the 1st of January.—*Med. Press and Circular.*

THE CHOLERA EPIDEMIC OF 1866 IN SWEDEN.—From the "Official Report of the Swedish College of Health on the Sanitary State of 1866," translated for the *Med. Times and Gazette* by J. W. Moore, M.B., we extract the following: There were 9,056 cases of cholera, and 4,389 deaths. This gives a mortality of 48.5 per cent. Of cholerine, 3,743 cases, and deaths 114. The disease was at its acme in virulence and frequency during the month of August, and after November only a few isolated cases occurred. Of 9,131 cases and 3,178 deaths—6 cases and 4 deaths belong to the month of June, 1,291 cases and 483 deaths to July, 3,366 cases and 943 deaths to August, 3,189 cases and 1,200 deaths to September, 1,160 cases and 508 deaths to October, 106 cases and 30 deaths to November, and 13 cases and 1 death to December. Of 4,096 cases and 1,405 deaths where the sex is reported, 2,151 cases and 729 deaths occurred in men; while 1,945 cases and 676 deaths occurred in women. Of 4,138 cases and 1,377 deaths, 675 cases and 290 deaths were those of children under 10 years; 278 cases and 82 deaths between 11 and 20 years; 1,093 cases and 295 deaths between 21 and 30 years; 905 cases and 259 deaths between 31 and 40 years; 642 cases and 209 deaths between 41 and 50 years; 380 cases and 149 deaths between 51 and 60 years; and 165 cases and 93 deaths over 60 years.

THE MONKEY SAID TO BE STRYCHNIA-PROOF.—A writer in the *Indian Medical Journal* states that the monkey is proof against strychnine.

FEMALE MEDICAL STUDENTS OF RUSSIA.—The Russian Government has decided to admit women into the Medical University of St. Petersburg, after passing an examination. They will be taught separately from the male students, and the whole course of study is limited to a period of four years. A diploma as midwife, which confers the right to practise, is to be given to those who go through all the prescribed examinations.

TRANSFIXION OF THE CHEST BY A LANCE.—There is now a patient at the Royal Victoria Hospital, Netley, laboring under aortic disease, who has recently recovered from the following remarkable lance-wound. He is a soldier of the 5th Royal Irish Lancers, and on the 1st of April, 1869, at Lucknow, was mounting his horse, when the animal reared on his hind legs. The butt of the lance was thrown forward and touched the ground, while the point of the weapon, unobserved by the man, was brought opposite to the lower part of the right side of his chest. Under these circumstances, the horse plunged forward, and the lance passed through the chest. The point entered over the cartilage of the seventh rib, and came out, together with twenty-two inches of the shaft, through the fossa infraspinata of the scapula, one inch and a quarter from its vertebral margin, and an inch and a half below the spine of the bone. No sooner had this occurred than the horse bolted, and it was not until he had gone about 120 yards that the man, grasping the lance with his right hand to take the drag off the chest, and reining up the animal with his left hand, was able to bring him to a standstill. As soon as the horse stopped, the man threw himself off, and in the act of falling to the ground the lance became partially broken or split up at the part which was close to the front wall of the chest. This added to the difficulty of extraction. The lower heavy part of the lance was first sawn off, and then about twenty inches of the part protruded beyond the scapula; the part within the chest was subsequently withdrawn by the aid of strong pincers. There was not much hemorrhage, and the man made an excellent recovery. The right side of the chest expands well, and, with the exception of loss of respiratory murmur and increased resonance over a limited space about the wound of entrance, the chest-sounds on this side are normal. The heart-disease was first noticed while he was under treatment for the wound just described. The length of the lance used by the 5th Lancers is nine feet three inches, and its weight is four pounds and a half.—*British Medical.*

THE PLASTER-OF-PARIS DRESSING.—Dr. James L. Little, of New York City, was the first—*Am. Med. Times*, Dec. 7, 1861—to recommend the plaster-of-Paris as an application in cases of club-foot "after tenotomy has been performed."

THE DISCOVERY OF THE CONVERSION OF STARCH INTO SUGAR.—In the year 1811, Kirchoff, a celebrated German chemist, discovered that it was possible to convert starch, by means of sulphuric acid, into sugar.

KIRSCHENWASSER.—This substance is obtained by the distillation of bruised cherries, and besides frequently containing prussic acid derived from the cherry stones, is a highly intoxicating liquor.

ANTIPHLOGISTIC TREATMENT IN DISEASES OF CHILDREN:

REMARKS BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION, APRIL 15 AND 22, AND MAY 27, 1870.

BY A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE II.

[Phonographically reported for the RECORD.]

COLD.

WHEN Ziemssen's book upon the application of cold appeared, some years ago, I began to use his plan of treatment, and I have followed it ever since. He places the patient in a bath, at first tepid, and then gradually cooled down until the desired temperature is reached. In this manner we may diminish the temperature in typhoid fever by as much as six degrees. Should it rapidly rise again, the bath must be repeated, and this as frequently as necessary to prevent its exceeding, say 103° or 104° F. I found a poor boy in Cherry street, burning with typhoid fever, at a temperature of 107°. I had him at once plunged into a cold bath for five or six minutes, and ordered this done every two hours so long as the temperature should rise suddenly after each bath. He got eight or ten of these plunges every day; the temperature fell to 98°, and never rose to its former height, and he recovered. I am confident that he could not have lived except for this reduction of temperature. In the hundreds of cases of typhus and typhoid where the treatment by cold has been tried, the mortality has been far less than under any other plan. This succeeds where everything else has failed.

In scarlet fever cold applications may be almost indispensable. In this fever the temperature will now and then rise to 106°, 107°, 108°, and this excessive heat alone prove the fatal element. Now I do not know any remedy that will reduce such a temperature and keep the patient alive except cold water—not to speak of cold air. Only this week I have seen such a case, where the thermometer in the rectum showed 108°. Every other means had been tried without effect. The child was placed in a warm bath, and cold water added till the bath stood at 64° and 60°. He was kept in the bath for two hours in the first twenty-four. To-day his temperature has not risen above 102°, and I consider him out of danger. I am sure that without the cold-water treatment he would have been lost. Of course there are many cases of scarlet fever in which the brain symptoms are so prominent that local cold applications are used by every one. But I am now alluding to the general cold-water treatment for the reduction of the general temperature of the blood.

In other eruptive fevers—in variola, for example—the same treatment would be good, though in the disease just named it looks a little strange to us, because we are not used to the practice. In the early part of this century a Hungarian writer alludes to the fact that, 'in the Transylvanian portions of the Austrian Empire, it is a common practice to place the variolous patient in a cold bath to reduce the fever; and he adds that the cases do as well under this treatment as under any other.

I would not give the impression that I think cold water a panacea or a remedy suitable for every age and condition. It may do much harm. If, for instance, there is one danger to the new-born infant greater than any other, it is that from the application of cold. I do not believe a baby should have a really cold bath until it has developed the faculty of locomotion, and the reactive power that comes with it. But the very shock that cold gives the system—the greatest, probably, that we can produce, except by the faradaic current—which makes it so dangerous to the young infant, renders it also invaluable in certain emergencies, as, for example, in asphyxia.

Cold applications have been recommended in the cephalæmatoma of the new-born, that is, hæmorrhage between the bone and the pericranium. Now it is a fact that this will get well if left to itself. We need not fear its spreading, for it will not extend beyond a suture. It is a fact, too, that the infant cannot bear the cold application, for a long period, without danger of collapse; it should, therefore, be used with caution. So, also, in the erysipelas of the very young cold applications may prove dangerous. Even in hyperæmia of the brain and its meninges, where cold is so frequently employed, I think it is possible to overdo the thing. Many of these cases are the result of changes in tissue, such as fatty degeneration, etc. In simple insolation cold is unquestionably of value from the shock it gives. It does good where we can see the shock produced; where we cannot, there is no use in continuing it. In several diseases of the nervous system—chorea minor, for instance—cold water has been used with advantage.

We must not forget that warm applications will also act antiphlogistically. It has been proved, by direct physiological experiments, that heat applied externally will reduce the temperature of the internal organs.

In the coryza of children I have used cold water, but not in the syphilitic form. I have learned from Dr. Peaslee to add common salt to the water in the treatment of chronic catarrh.

A large number of cases of ophthalmia in the new-born will get well under ice applications alone—a cloth taken directly from a lump of ice and placed on the eyes every half minute, and this continued not for hours but for days. I have seen very many cases of diphtheritic ophthalmia—many where the eye was destroyed—and the only cases which did well were the ones in which ice was used. Furthermore, I would not consent to be without ice in diphtheria or croup; and for many years my local treatment of these two diseases has consisted almost exclusively in its use, both externally and internally, especially the latter, where there is much pharyngeal affection.

If there is anything which I should rely upon in pneumonia, especially lobar pneumonia, where the fever is very high, it is cold-water treatment. If the temperature reaches 106°, 107°, pack the patient every hour or two. Under this cases have done well that I had almost despaired of. In most instances, however, cold local applications, changed every few minutes, will suffice. Not only in lobar pneumonia, but also in many cases of bronchitis and catarrhal pneumonia, may cold be relied upon.

In acute heart diseases, with the consecutive præcordial pain, cold applications over the region of the heart, and reaching down to that of the stomach, will almost always do good. In synovitis, and especially rheumatic synovitis, cold will do good in nearly eve y case, and I see no contra-indication to its use.

I need not add that local inflammation within reach indicates the application of cold; thus local phlegmon from any cause, inflammation of glands, peritonitis, etc. I should, however, try your patience too much by enu-

merating all the forms of disease in which this remedy, because it does great service, is indispensable. It will be our duty to overcome whatever there is left of prejudice in the minds of the public against it. The time has arrived already when no objection is raised any more to allowing windows to be opened in a sick-room. It will, I hope, be not long before the claims of circulation will be acknowledged like those of respiration.

ACIDS.

Among antiphlogistics, the acids are frequently mentioned; and it is certain that, besides their property of quenching thirst, some of them have the effect of reducing the pulse and the temperature. It appears that the organic acids act better than the mineral acids; indeed, these latter seem sometimes to increase the temperature somewhat, while the former will both render the heart's action slower, and reduce the temperature to a certain extent; hence they are preferably indicated in inflammatory diseases.

There is one point not to be forgotten in the use of acids of either kind, that, if too long persisted in, they will deteriorate the quality of the blood by disintegrating the red corpuscles. Thus, when given in typhoid fever, the acids act very favorably in the beginning, but they appear to protract convalescence, from their effect upon the blood.

SALTS.

A few words concerning the exhibition of salts in inflammatory diseases. There is no established rule with regard to their effect upon the heart's action; nor is there any theory of their action upon this or that nerve; and there are but few established facts upon which to build a theory. The salts of potassa will lower pulse and temperature, and their effect is not produced through the pneumogastric nerve. So with the tartrate of potassa and antimony, it appears to act, not upon the pneumogastric nerve, but upon the heart directly, perhaps by influencing its ganglia.

If a salt be administered in concentrated solution, this will act by osmosis upon the capillaries of the intestinal tract, and deprive the blood of a large amount of serum, including, of course, albumen. Thus salts will never be given for any length of time in a disease without impairing the constitution of the blood, and rendering convalescence slower. We must therefore avoid not only strong salts, but even the mild salina, as antiphlogistics, though we may use them as purgatives. But for any speedy derivative effect we require stronger purgatives than these, and should rely upon elaterium or croton oil.

COUNTER-IRRITANTS.

Another mode of treatment very frequently resorted to is that by cutaneous irritation, which may act in two different ways—either directly upon the nervous system, or upon the circulation. It has been proved beyond a doubt that strong irritation of the cutaneous nerves, or of others, will produce first a brief period of general irritation, and afterwards a reduction of temperature and pulse. On the other hand, feeble, though long-continued, irritation of the nerves produces only the general irritation, and not the reduction of pulse and temperature characteristic of the more powerful irritants. Thus it appears that when the electric brush is applied to the skin over a large surface, both pulse and temperature will come down almost immediately. I have myself been present when Prof. Heidenhayn related his experiments showing the same effect, in dogs, from irritation of the crural nerve.

Epispastics.—The question comes up, whether those irritants we generally resort to will have any such powerful effect as this of the electric brush; whether we can expect the same speedy result from epispastics, for instance. I think not. Not only will epispastics give no such immediate and powerful depressing action as will the electric brush, but we expect from them more of the protracted general irritation than we get from this. Indeed, I have found epispastics, in the cases, and at the periods, of inflammatory disease where they are usually applied, worse than useless. In the first stage of pneumonia, for example, children are very restless, and counter-irritation to the skin will only render them more so, and still further prevent sleep; they will cry themselves into more fever and more violent pulmonary action, and, so, much harm may be done. Finding this my almost uniform experience, and moreover seeing no great benefit to come from epispastics in the first stage of pneumonia or other inflammatory diseases, I long ago gave them up.

But there is a stage when epispastics may be indicated—when, for instance, hepatization has become established, absorption is not taking place readily, and we have reason to fear suppuration. In such a case I think an epispastic may do good, simply as an irritant—to light up a new focus of irritation, give a fresh start to the circulation, and so, as it were, set the ball a-rolling. By the freeing of the circulation the first step is taken toward absorption.

Here I may speak of tincture of iodine, mustard plasters, mustard baths, purgatives, diaphoretics, diuretics. For, in my opinion, it is the counter-irritant effect which we seek even from an epispastic when we employ it at all.

Tincture of iodine I do not use to the extent which I have often seen in other hands. I have seen it applied over every inflammatory swelling of the glands, even over the inflamed vertebral column, and over chronic peritonitis, chronic pleurisy, etc. I confess that I do not use it in most of these cases, though I have often done so in articular inflammations, and now and then in acute inflammation of a gland. I think that in all these cases it acts as a local irritant, by stimulating the surface, dilating the superficial blood-vessels, and, may be, also by irritation of the cutaneous nerves. For I believe that more effects in medicine are due to the cutaneous nerves than we commonly attribute to them. For instance, we recommend bathing in mineral waters—in chalybeate, carbonic-acid, or salt, waters—and we see its good effects, though we know that the epidermis is impermeable to liquid, and requires a good deal of preparation to render it permeable. The good effects we see from such baths must be due simply to the excitation of the cutaneous nerves; and the same, I have no doubt, is true of tincture of iodine, etc., in many cases. I have certainly seen good results from iodine in subacute inflammations of the joints.

Mustard plasters I rely upon a good deal in the inflammations of children. I have repeatedly alluded to the necessity of saving blood and saving strength in these cases; and if we can obtain the same derivant effect from a mustard plaster that we can from an epispastic, we should certainly resort to the milder remedy. Moreover, as these local irritants depend for their effect more upon their influence on the nerves than upon that on the circulation, I think the frequent repetition of a mustard plaster over an inflamed lung or pleura will do more good than a blister, put on once and allowed to remain and keep the child from rest. My usual mode is to mix the mustard pure; to apply it over the whole chest, both in front and behind; allow it to remain three or four minutes, until the skin is pink and nothing more; let the child rest an hour or two; and then apply again. The children do not suf-

fer much. In cases of pneumonia in the very young, it is desirable that the infants should cry now and then, inasmuch as the danger is greater from collapse in the healthy lung than from the inflammatory process in the affected one; and so I apply the mustard to make them cry. I have been very well satisfied with this plan of treatment, which I have followed for many years.

The *mustard bath*, especially the mustard foot-bath, is very good so far as it goes; when the distribution of blood is faulty it is certainly excellent. General mustard bathing I have now and then resorted to in severe inflammations of the lungs, as well as in those of the brain. I have prepared a hot bath and thrown mustard into it *ad libitum*, in order to produce a very powerful derivation to the skin in a very few minutes; and I think it has had most beneficial results.

The effect of *purgatives*, *diaphoretics*, *diuretics*, is about the same, only upon different portions of the integument; for the mucous membranes of the body must be considered only as continuations of the external skin. The fact that upon the lips, etc., we have a transition between the two proves them of essentially the same character. Thus it happens that we have the same diseases of both; and thus it is that the effect of purgatives and diuretics upon the internal integument is the same as that of mustard plasters and epispastics upon the external, only that purgatives act much more promptly and efficiently than these last, since the mucous membrane of the intestinal tract offers so very large a surface for their action. A powerful purgative coming in contact with this extensive mucous membrane amounts to much more than tincture of iodine or an epispastic to the skin.

Up to this moment, gentlemen, you must admit that I have not deserved the remark of Dr. Elliot, last Friday, that there had been a growing difference between us in our methods of giving medicine; that I had been coming to have more and more faith in powerful medication, while he had been learning to trust more to nature. Up to this moment I have been rather impressing upon you the necessity of discarding the usual medicines and applications; I have spoken disparagingly of blood letting, epispastics, etc., and have found few opportunities to recommend dosing at all, and none to advocate heavy dosing. But there are several remedies of which I mean to speak for large doses, or rather for sufficient doses, as I understand them. It will hardly be necessary to recall what I said of the rapidity with which inflammatory diseases, and the fever following them, develop in childhood; of the danger attending this rapid development; and of the necessity, therefore, if you are to do anything for these diseases, of doing it speedily and effectively. The expectant method is that which lets good alone and lets bad alone. As soon as we have arrived at a clear diagnosis I think we ought to act accordingly, and not allow a pathological process to run its own course. Therefore, so far as the antifebriles are concerned—veratrum, digitalis, camphor, quinine, ergot, etc.—I am in favor of giving them in sufficient doses. A good deal has been written, of late, upon these drugs, and very various doctrines are held concerning their effects. But, as it is our object only to establish a few clinical landmarks, and not to sift the numerous physiological experiments upon these remedies, I shall simply state what has been my habit in administering them in the diseases of children.

DIGITALIS AND VERATRUM VIRIDE.

From all that I have been able to learn by a comparison of the literature of the last twenty years, and especially since Traube published his experiments upon digitalis, it seems to me we must consider that digitalis and veratrum act upon the pneumogastric nerve. We know that when the pneumogastric nerve is paralyzed, whether from severing in its course or from destruction of its root in the brain, the action of the heart becomes uncontrollable. We see this uncontrollable action of the heart in the last stage of pneumonia, and late in acute meningitis. When this last disease has continued for some weeks after its characteristic symptoms due to irritation of the brain, all at once there sets in an increased cardiac action, with increase of temperature, etc. This is the result of paralysis of the root of the pneumogastric in the brain. On the contrary, when the pneumogastric nerve is irritated,—as in the beginning of this very disease, in commencing meningeal effusion, in tubercular meningitis,—we have the pulse slow, though perhaps irregular.
